Galactose Metabolism in Regenerating Rat Liver

By CHRISTIAN H. BAUER, BARBARA F. HASSELS and WERNER G. REUTTER
Biochemisches Institut, Universität Freiburg, D-78 Freiburg, Germany

(Received 11 July 1975)

1. Rats trained on a controlled lighting and feeding schedule were subjected to partial hepatectomy or sham operation. 2. After a lag period of about 6 h the activity of UDP-galactose 4-epimerase increased threefold, reaching a maximum 4 days after partial hepatectomy, and returned to normal values within a fortnight. 3. The enzyme pattern of the UDP-galactose–glycoprotein galactosyltransferase was biphasic, one peak appearing at 20 h, the second at 72 h after partial hepatectomy. 4. The rise in enzyme activities could be blocked by the injection of actinomycin D, and the K_m values for UDP-glucose and UDP-galactose were nearly identical in regenerating and adult liver. It is therefore concluded that the increase in enzyme activity is due to synthesis de novo of enzyme protein. 5. UDP-glucose and UDP-galactose were determined at different times after partial hepatectomy. The lowest concentration was found between 3 h and 6 h after operation (UDP-glucose: 232±32 nmol/g of liver; UDP-galactose: 72±10 nmol/g of liver); the highest value was measured between 24 h and 72 h (UDP-glucose: 385±28 nmol/g of liver; UDP-galactose: 108±9 nmol/g of liver). 6. In unoperated animals the epimerase and galactosyltransferase exhibited daily oscillations, with maximum values at the end of the dark period.

Liver has the capacity to regenerate; within 7 days after partial hepatectomy the original liver weight is nearly restored. The mechanism responsible for the initiation of regeneration is still unknown, though extensive investigations have been undertaken to elucidate the sequence of events leading to cell division (Mayfield & Bonner, 1972; Paul et al., 1972; Bucher & Swaffield, 1973). Several reports have shown that RNA and DNA synthesis is induced by partial hepatectomy (Grisham, 1962; Chaudhuri & Lieberman, 1968; Bucher & Swaffield, 1969). At the same time the activity of a number of enzymes increases which are not involved in RNA or DNA synthesis. Among these are pyruvate kinase (EC 2.7.1.40) (Bonney et al., 1973), ornithine decarboxylase (EC 4.1.1.17) (Russell & Snyder, 1968; Jänne & Raina, 1968), alkaline phosphatase (EC 3.1.3.1) (Pekarthy et al., 1972), acid phosphatase (EC 3.1.3.2) (Chatterjee et al., 1974) and glutamine–fructose 6-phosphate aminotransferase (EC 5.3.1.19) (Akamatsu & Maeda, 1971). Nothing is known about the activity of galactose-metabolizing enzymes during liver regeneration.

The present study has been undertaken to characterize the role of galactose metabolism in regenerating rat liver, because galactose is an integral constituent of glycoproteins (Eylar & Jeanloz, 1962) and glycolipids (Henning & Stoffel, 1973). It was decided to find out whether galactokinase (ATP–d-galactose 1-phosphotransferase, EC 2.7.1.6) and uridylyltransferase (UDP-glucose–α-d-galactose 1-phosphate uridylyltransferase, EC 2.7.7.12) respond to surgical removal of two-thirds of the liver. Since galactose is only a minor nutrient for adult animals, the necessary supply of this essential carbohydrate is obtained via the conversion of UDP-glucose into UDP-galactose, a reaction which is catalysed by UDP-galactose 4-epimerase (EC 5.1.3.2). UDP-galactose is the substrate for the galactosyltransferase (UDP-galactose–glycoprotein galactosyltransferase) which attaches the galactose molecule to the nascent glycoprotein. Therefore the galactosyltransferase and the UDP-galactose 4-epimerase have been studied more thoroughly as a function of time after partial hepatectomy, with special attention to normal diurnal rhythms.

Materials and Methods

Materials

Animals. Male Wistar rats (Ivanovas, Kisslegg, Germany), weighing about 210 g each, were fed on a commercial diet (Altromin; Altromin G.m.b.H., Lage-Lippe, Germany) and water given ad libitum. The diet contained 18–20% (w/w) of protein. The animals were kept in windowless rooms at 20°C with constant humidity, and light from 07:30 to 19:30 h. Food was only available during the dark period.

Chemicals. UDP-[14C]galactose (245 mCi/mmol), d-[1-14C]galactose (40 mCi/mmol), d-[U-14C]galactose 1-phosphate (200 mCi/mmol) and [14C]toluene were obtained from The Radiochemical Centre,
Amersham, Bucks., U.K. The substrates UDP-galactose, UDP-glucose, galactose 1-phosphate, the coenzymes ATP and NAD+, and the enzyme UDP-glucose–NAD+ oxidoreductase (EC 1.1.1.22) were supplied by Boehringer Mannheim G.m.b.H. (Mannheim, Germany). Fetuin from foetal calf serum and dithiothreitol came from Sigma Chemical Co. (St. Louis, Mo., U.S.A.). Actinomycin D was bought from Bayer A.G. (Werk Elberfeld, Germany) and bovine serum albumin (electrophoretic purity 100%) was from Behringwerke A.G. (Marburg/Lahn, Germany). All other chemicals of analytical grade were obtained from E. Merck A.G. (Darmstadt, Germany).

**Methods**

Partial hepatectomy and sham operation. After 3 weeks of a controlled lighting and feeding schedule, partial hepatectomies (Higgins & Anderson, 1931) were performed between 08:30 and 10:00h, two-thirds of the liver being removed while the animals were kept under light ether anaesthesia. Control animals were subjected to sham operations by opening the abdominal cavity by a midline incision. Before the cavity was closed again, the liver was pulled out for a moment.

Preparation of cell extract. The livers were quickly removed while the animals were under light ether anaesthesia. The tissue (1–2 g) was transferred to 4 vol. of chilled homogenizing medium, containing potassium phosphate (50 mM), EDTA (5 mM), N-acetylcysteine (4 mM), bovine plasma albumin (0.1 mg/ml) adjusted to pH7.5 with 1M-NaOH (Walker & Khan, 1968). The tissue was homogenized for 40–50 s with a Torpedo homogenizer (Emmendingen Maschinenbau G.m.b.H., Emmendingen, Germany) equipped with a thyristor regulator (Janke und Kunkel K.G., Staufen, Germany). Portions of this homogenate were used for the determination of UDP-galactose–glycoprotein galactosyltransferase activity. The mixture was centrifuged for 30 min at 30 000 g.

The supernatant fraction was diluted by addition of 4 vol. of the phosphate buffer described above (pH7.5). All enzymes were assayed within 2 h after removal of the liver.

**Assays.** The galactokinase (ATP–d-galactose 1-phosphotransferase, EC 2.7.1.6) was measured by a radiochemical assay as described by Sherman & Adler (1963). The standard assay mixture in a final volume of 0.2 ml (pH8) contained glycyglycine (25 μM), ATP (1 μM), MgCl2 (1.5 μM), NaF (1 μM), dithiothreitol (0.8 μM), d-[1-14C]galactose (0.2 μM) and approx. 30 μl of supernatant fraction (0.14–0.20 mg of protein). Incubations were carried out for 10 min at 30 °C. The reaction was terminated by placing the Eppendorf cups in boiling water for 90 s. Afterwards 100 μl of the assay mixture was applied to Whatman no. 3 paper and chromatographed for 18–20 h with ethanol/1M-ammonium acetate, pH7.5 (5:2, v/v) (Paladini & Leloir, 1952). Blank incubation mixtures contained no ATP. The amount of radioactivity was determined by counting successively 1.0 or 2.0 cm-wide strips in 15 ml of toluene scintillation mixture (Kallmann et al., 1958). The unit of specific activity is expressed in nmol of d-galactose 1-phosphate formed/min per mg of protein.

For the determination of the galactose 1-phosphate uridylyltransferase (UDP-glucose–α-d-galactose 1-phosphate uridylyltransferase, EC 2.7.7.12) a similar procedure was used (Bertoli & Segal, 1966). Incubation mixtures in a final volume of 0.2 ml (pH8.5) contained glycine (25 μM), UDP-glucose (50 nmol), dithiothreitol (2 μM), d-[U-14C]galactose 1-phosphate (68 nmol) and approx. 30 μl of supernatant fraction. Blank incubation mixtures contained no UDP-glucose. For the separation and determination of UDP-[14C]galactose the same methods were used as described for the galactokinase. Units of specific activity are given as nmol of UDP-[14C]galactose formed/min per mg of protein.

UDP-galactose 4-epimerase activity (EC 5.1.3.2) was measured spectrophotometrically by following the formation of NADH at 334 nm and 30 °C (Maxwell, 1957). The assay mixture (pH8.7) contained NAD+ (1.3 μM), UDP-galactose (0.14 μM), glycine (350 μM) and UDP-glucose dehydrogenase (0.1 unit) in a final volume of 0.75 ml. The reaction was initiated by the addition of UDP-galactose and observed for 5 min.

The activity of the UDP-galactose–glycoprotein galactosyltransferase, a marker enzyme of the Golgi apparatus, was measured in a radiochemical assay with desialylated and degalactosylated fetuin (see below) as acceptor. The total volume of the incubation mixture (pH6.75) was 0.1 ml, containing sodium cacodylate (6 μM), MnCl2 (1.2 μM), MgCl2 (0.2 μM), dithiothreitol (1 μM), UDP-d-[1-14C]galactose (0.1 μM), fetuin (0.5 mg), 10 μl of 5% (v/v) Triton X-100 and 20 μl of the liver homogenate (0.3–0.4 mg of protein). Blank incubation mixtures contained native fetuin. Incubation was carried out for 30 min at 30 °C. The reaction was stopped by placing the Eppendorf cups in boiling water for 90 s. The protein-bound radioactivity was determined by the method of Mans & Novelli (1960) with slight modifications. The incubation mixture was pipetted on to filter-paper discs (Whatman 3 MM, 2.3 cm diam.) which had been mounted on pins. The discs were dried and transferred to chilled 10% (w/v) trichloroacetic acid to precipitate the protein. The discs were left for 60 min at 4 °C and then subjected to the following washing procedure: 30 min at 4 °C in 5% (w/v) trichloroacetic acid, 30 min at 22 °C in ether/1976
ethanol (1:1, v/v), and finally 15 min in ether. Radioactivity was determined by counting the air-dried discs in toluene scintillation mixture.

Preparation of desialylated and degalactosylated fetuin. Sialic acid was removed from foetal calf serum fetuin by acid hydrolysis with 0.02M-H2SO4 for 60 min at 80°C. Galactose was removed by the method of Spiro (1964), which involves periodate oxidation, borohydride reduction and mild acid hydrolysis.

Determination of sugar nucleotides. UDP-glucose and UDP-galactose were determined essentially as described by Keppler et al. (1970). Liver samples were obtained in situ by the freeze-clamp technique (Wollenberger et al., 1960). The frozen tissue was transferred to 3 vol. of chilled 0.9M-HClO4 and immediately homogenized with a motor-driven Potter–Elvehjem homogenizer and Teflon pestle for 1 min at 3000 rev./min. The suspensions were centrifuged for 15 min at 18000g, the supernatants being carefully decanted and collected, whereas the sediments were rehomogenized in 1.5 vol. of 0.6M-HClO4. After a second centrifugation the supernatants were combined with the first ones and neutralized with KOH until a pH of 7.5 was reached. KClO4 was removed by centrifugation for 10 min at 10000g and the clear supernatant was used for the determination of sugar nucleotides. The standard assay mixture in a final volume of 0.7ml (pH 8.5) contained glycine (500μmol), NAD+ (1.5μmol), EDTA (4μmol) and 200μl of neutralized liver extract. The reaction was initiated by the addition of UDP-glucose dehydrogenase (0.1 unit). When no further increase of extinction could be observed UDP-galactose 4-epimerase (0.1 unit) was added to determine the content of UDP-galactose.

Protein determination. The protein content of the supernatant fraction was determined by the method of Lowry et al. (1951). For homogenates the biuret method was preferred (Beisenherz et al., 1953). Before the addition of biuret reagent, protein was precipitated either by 10% (w/v) trichloroacetic acid or by dioxan. Crystalline bovine serum albumin was used as a standard.

Results

UDP-galactose 4-epimerase. After a lag period of about 6h, the activity increased threefold, reaching a maximum of 15nmol/mg of protein 4 days after partial hepatectomy (Fig. 1). Sham-operated animals showed no striking changes. Only a slight increase in enzyme activity was measured within 24h after operation, which gradually declined thereafter.

When the activity is expressed in nmol/g wet wt. of liver the enzyme pattern does not change, except that at day 4 after partial hepatectomy only a 2.6-fold increase of epimerase activity is calculated. This fact is a result of increased protein concentration. Up to 24h after partial hepatectomy the protein content/g wet wt. of liver decreased, and remained at this low value for another 24h before it started to rise. Usual concentrations of protein were attained approx. 14 days after partial hepatectomy (Fig. 2). The effect of UDP-galactose on epimerase activity was determined and the data obtained were plotted by the method of Lineweaver & Burk (1934). The Michaelis constants were calculated as 30μM for rat liver epimerase 4 days after partial hepatectomy and 32μM for the epimerase of sham-operated animals.
**UDP-galactose-glycoprotein galactosyltransferase.**

Fig. 3 shows that the specific activity of the galactosyltransferase exhibits two peaks, the first occurring 20h and the second 72h after partial hepatectomy. It is remarkable that after the first maximum a pronounced decrease occurred, reaching a minimum between 24 and 32h which was less than 25% of the value for non-operated controls. To exclude the possibility that the low activity was due to an increase in inhibitor concentration, a mixing experiment was performed. Homogenate prepared from rats 26h after partial hepatectomy was added to control extracts, with the result that no inhibition of the galactosyltransferase was found.

During the first 24h a similar pattern of galactosyltransferase was found in sham-operated animals. However, in contrast with partially hepatectomized rats the enzyme activity at 72h did not exceed normal values.

The $K_m$ value was calculated to be 59 $\mu$M-UDP-galactose for the galactosyltransferase of sham-operated animals. After partial hepatectomy no change of $K_m$ was found.

**Diurnal rhythm.** When investigating the pattern of enzymes it is necessary to know their normal daily rhythm, because a change after partial hepatectomy may only reflect diurnal variation of enzyme activity. Under a controlled lighting and feeding schedule the epimerase as well as the galactosyltransferase showed their highest activity at the end of the dark period between 07:00 and 08:00 h (Fig. 4). During the day, when the animals were resting, the enzyme activity decreased. Yet the lowest values were not found at 19:30 h, when the light was switched off and food was available again, but between midnight and 04:00 h.

**Effect of actinomycin D on enzyme activity.** To prove a direct relationship between RNA synthesis and the increased activities of the epimerase and galactosyltransferase, the rats received a single injection of 1 mg of actinomycin D/kg body wt. (Fig. 5). When actinomycin is injected immediately after partial hepatectomy (Short et al., 1975) it can most effectively suppress the increase of enzyme activity. At 24h after the operation the activity of the epimerase was inhibited by 50%, compared with operated animals which received no antibiotic, but an injection of 0.9% NaCl/ethanol. When actinomycin was administered at a later time it could still block the stimulation of enzyme activity, but only to a lesser extent.

Concerning the galactosyltransferase, the administration of actinomycin D can even induce a limited superinduction. At 4 and 5 days after partial hepatectomy (the antibiotic was injected 18h before death) the activity of the galactosyltransferase was 20% higher as compared with controls. This finding will be discussed below in more detail. There was little effect of actinomycin D on the enzyme activity in sham-operated rats.
Galactokinase and galactose 1-phosphate uridyltransferase. The activities of both enzymes increased after operation but in contrast with the epimerase and galactosyltransferase there was hardly any difference between the enzyme patterns after partial hepatectomy and sham operation. The galactokinase activity increased 2.5-fold within 24 h, whereas the uridyltransferase activity rose only by 20% as compared with sham-operated controls.

Concentration of sugar nucleotides. The substrates for the epimerase and galactosyltransferase, UDP-glucose and UDP-galactose respectively, were measured at different times after partial hepatectomy (Table 1). Immediately after the operation the concentration of UDP-glucose decreases, reaching a minimum of 70% of the normal value between 3 and 6 h. This intracellular loss is compensated for at 16 h after partial hepatectomy. The decrease in UDP-glucose is almost paralleled by UDP-galactose, with the consequence that the ratio UDP-glucose/UDP-galactose remains in the normal range of 3.2–3.7:1.0. In comparison with partial hepatectomy, sham operation produces a rise to higher concentrations of both sugar nucleotides. Already 3 h after operation normal values are reached again, followed by a shorter-lasting overshoot of the values for UDP-glucose and UDP-galactose.

Discussion

Since galactose is an essential constituent of membrane glycoproteins and glycolipids, studies on galactose metabolism may contribute to an understanding of processes initiated in regenerating rat liver.

After a lag period of about 6 h, probably owing to operation stress, the activity of galactose-metabolizing enzymes increases. Partial hepatectomy caused a threefold increase in the activity of UDP-galactose 4-epimerase, with a maximum 4 days after operation. The enzyme pattern of the galactosyltransferase was biphasic, the first peak of activity appearing at 20 h after partial hepatectomy, the second at 72 h.

Table 1. Time-course of sugar nucleotide concentration

Partial hepatectomies and sham operations were performed between 08:30 and 10:00 h. At the times indicated, liver lobes were instantly frozen in situ between metal tongs precooled in liquid N₂ (Wollenberger et al., 1960). The sugar nucleotides were determined in a neutralized HClO₄ extract. For further experimental details see the Materials and Methods section. Values are means± s.d. from five rats. *P<0.01 as compared with sham-operated animals.

| Time after operation (h) | UDP-glucose | | UDP-galactose | |
|-------------------------|-------------|-----------------|----------------|
|                         | Partial hepatectomy | Sham operation | Partial hepatectomy | Sham operation |
| 1                       | 273 ± 20     | 235 ± 28        | 90 ± 8          | 84 ± 10        |
| 3                       | 232 ± 32*    | 322 ± 18        | 72 ± 10         | 87 ± 4         |
| 6                       | 243 ± 35*    | 338 ± 30        | 73 ± 13         | 102 ± 10       |
| 10                      | 294 ± 27*    | 417 ± 40        | 90 ± 7          | 129 ± 15       |
| 24                      | 385 ± 28     | 404 ± 32        | 108 ± 9         | 110 ± 12       |
| 48                      | 378 ± 34     | 357 ± 30        | 105 ± 9         | 94 ± 9         |

| Control (unoperated animals) | 331 ± 25 | | 92 ± 7 |

Vol. 154
The data presented here show quite clearly that the rise in enzyme activity is due to synthesis of enzyme protein de novo. Actinomycin D, a potent inhibitor of protein synthesis, blocked the increase completely, provided that the antibiotic was administered immediately after partial hepatectomy. At a later point of time actinomycin D is less effective. Akamatsu & Maeda (1971) reported a similar result for glucosamine 6-phosphate synthetase. Moreover, when actinomycin D is injected 4 days after partial hepatectomy, the activity of galactosyltransferase does not decrease, but increases further. This phenomenon, referred to as superinduction, was first described for tryptophan pyrrolase (Garren et al., 1964). It may be possible that after partial hepatectomy, when the activity of galactosyltransferase is maximal, an actinomycin-sensitive repressor appears. By blocking the synthesis of this repressor, the activity of the galactosyltransferase is raised. Further work is required to solve this problem.

Not only the inhibition experiments with antibiotics but also the determination of enzyme characteristics support the conclusion that there is synthesis of enzyme protein de novo. The $K_m$ values for the epimerase and galactosyltransferase in both normal and regenerating liver show no differences. On the basis of these findings it is unlikely that the increased activity of enzymes after partial hepatectomy is caused by modifying effectors.

Rapid proliferation of hepatocytes is found normally in foetal and neonatal rat liver. Therefore it is interesting to compare the characteristics of galactose-metabolizing enzymes in perinatal and adult rats with those results obtained after partial hepatectomy. The activities of galactokinase (Cuatrecasas & Segal, 1965) and of galactose 1-phosphate uridylyltransferase (Bertoli & Segal, 1966) increase a few days before birth and reach a maximum at 5–10 days of age respectively. No evidence of enzyme heterogeneity could be found, and the $K_m$ values and other kinetic parameters of the galactokinase remain constant during development (Walker & Khan, 1968). Similar results are reported for the UDP-galactose 4-epimerase (Cohn & Segal, 1969) and UDP-galactose-glycoprotein galactosyltransferase (Jato-Rodriguez & Mookerjea, 1974), except that these enzymes show their highest activities in the perinatal period and decrease rapidly within a few days. The $K_m$ value of 55 $\mu$M-UDP-galactose for both foetal and adult liver galactosyltransferase does not differ from data obtained after partial hepatectomy.

It is noteworthy that not only the epimerase and galactosyltransferase change their activity after partial hepatectomy, but at the same time alterations in the concentration of sugar nucleotides are found. The decrease in UDP-glucose and UDP-galactose immediately after operation is not due to enhanced accumulation of glycogen in the liver remnant. On the contrary, up to 24h after operation the glycogen content decreases, and returns to normal after 48 h (Bonney et al., 1973). It is more likely that the lowered content of UDP-glucose is caused by a decreased rate of synthesis. It is known that the hexokinase activity increases (Lea et al., 1970) and phosphoglucomutase activity remains constant (Weber & Cantero, 1957) after partial hepatectomy. Moreover, the coenzyme UTP, necessary for the synthesis of UDP-glucose, increases by 50% within 3h after partial hepatectomy (Bucher & Swaffield, 1969). The major part of the glycogen in the liver remnant is used either by glycolysis or to maintain a sufficient blood glucose concentration.

This work was supported by the Deutsche Forschungsgemeinschaft, Bad Godesberg, Germany.
