(Received 21 March 1978)

Adenylate deaminase (AMP deaminase, EC 3.5.4.6) of a high substrate specificity was purified from pig heart by chromatography on cellulose phosphate. The enzyme shows a co-operative binding of AMP [h (Hill coefficient) 2.35, with s0.5 (half-saturating substrate concentration) 5 mM]. ATP and ADP act as positive effectors, lowering h to 1.55 and s0.5 to 1 mM. The addition of liposomes (phospholipid bilayers) to ATP-activated or ADP-activated enzyme causes a further shift of the h value to 1.04 and s0.5 to 0.5 mM. For ATP-activated enzyme the addition of liposomes increases Vmax by about 100%, and for ADP-activated enzyme by 50%. Liposomes have no effect on the kinetics of AMP deaminase in the absence of ATP and ADP, and neither do they influence the inhibitory effect of orthophosphate on heart muscle AMP deaminase. Metabolic implications of these findings are discussed.

The purine nucleotide cycle (Lowenstein, 1972) is a metabolic pathway of special importance for heart physiology (Żydo wo, 1976). Adenylate deaminase (EC 3.5.4.6), the NH3-forming enzyme in the cycle, has been found in the cytosol of most vertebrate tissues (Purzycka & Żydo wo, 1960; Purzycka 1962; Ogasawara et al., 1974, 1975). In skeletal muscle it is partly complexed with myosin (Currie & Webster, 1962; Byrnes & Suelter, 1965; Żydo wo et al., 1974; Ashby & Frieden, 1977). The association of some other enzymes with either natural membranes (Entman et al., 1977) or with artificial phospholipid vesicles (Wooster & Wrigglesworth, 1976) has been shown to influence the catalytic properties of the enzyme. Adenylate deaminase from the heart has been little investigated so far (e.g. Chung & Bridger, 1976), and any factor influencing the regulatory properties of this enzyme might affect the operation of purine nucleotide cycle in the heart. One of the factors influencing either the activity or the regulatory properties of any soluble cytosolic enzyme may be its reversible association with intracellular membranous structures. Liposomes are frequently used as a model that may mimic the effect of natural membranes.

In the present paper it is shown that, although liposomes, the phospholipid-containing model membrane structures, do not influence the non-activated kinetics of adenylate deaminase from pig heart, they increase very strongly the activating effect of ATP and ADP on this allosteric enzyme.

Materials and Methods
Adenosine, AMP, ADP, ATP, adenosine 2'-phosphate, adenosine 3'-phosphate, dAMP, CMP and CTP were purchased from Sigma Chemical Co., St. Louis, MO, U.S.A. Cyclic AMP was from Schuchard, München, Germany; cellulose phosphate P-11 was from Whatman, Maidstone, Kent, U.K. Egg phosphatidylcholine (lecithin) was obtained from Serva, Heidelberg, Germany; phosphatidyl ethanolamine (from egg) and phosphatidic acid (from egg phosphatidylcholine) were from Koch-Light, Colnbrook, Bucks., U.K. Adenosine 5'-phosphoroamidate and adenosine 5'-sulphate A grade were obtained from Calbiochem, San Diego, CA, U.S.A. All other chemicals were of highest analytical grade obtainable from P.O.Ch., Gliwice, Poland.

Enzyme preparation
AMP deaminase from pig heart was purified by cellulose phosphate chromatography essentially as described by Smiley et al. (1967) for the skeletal-muscle enzyme, with slight modifications. All the steps were performed at 4°C instead of at room temperature, the extraction was carried out by stirring the homogenate for 12 h, and the adsorption on cellulose phosphate was prolonged for 1 h. The elution profile from cellulose phosphate is shown in Fig. 1. The enzyme obtained was stable for at least 1 month when stored at 4°C, and it showed optimum activity at about pH 6.5 in potassium succinate buffer. It was very specific, no deamination of 2'-AMP, 3'-AMP, cyclic 3':5'-AMP, dAMP, ATP, CMP, CTP, adenosine 5'-phosphoroamidate, adenosine 5'-sulphate or adenosine being detected even when incubated with these compounds for 60 min.

Enzyme assay
The incubation mixture, in a final volume of 0.5 ml, contained 100 mM-potassium succinate buffer,
The heart-muscle extract and phosphocellulose column were prepared as described by Smiley et al. (1967). Elution was carried out with 1 M-KCl, pH 7, at 4°C. The flow rate was 10 ml/h; 5 ml fractions were collected. O, Protein concentration (mg/ml); ●, specific activity (μmol of NH₃/min per mg of protein). From the extract containing 13 200 mg of protein, 3 mg of the purified enzyme was obtained. The purification factor was about 850 and the yield of the enzyme activity 19%.

pH 6.4, 150 mm-KCl, 5–10 μg of enzyme protein, AMP, and other additions as indicated in the Figures. The incubation was carried out for 10 min at 30°C; the reaction was started by the addition of enzyme solution, terminated by the addition of phenol reagent and the NH₃ liberated was determined. About 4–5 mg of protein was contained in the incubation mixture when crude extracts were assayed for enzyme activity. In this case the incubation was terminated by the addition of an equal volume of 15% (w/v) trichloroacetic acid, the solution was neutralized with KOH, and NH₃ was determined in a portion of the clear supernatant.

For the investigation the effect of liposomes, 25–50 μl of enzyme solution containing 5–10 μg of protein was preincubated for 1 h at 4°C with 250 μl of liposome suspension containing 375 nmol of phospholipid phosphorus, potassium succinate buffer and KCl. In this case, the reaction was started by the addition of an appropriate amount of AMP solution, to make up the final volume of the incubation mixture to 0.5 ml.

Preparation of liposomes

Positively charged, negatively charged and neutral liposomes were prepared essentially as described by Galla & Sackmann (1975). The positively charged liposomes contained phosphatidylcholine and phosphatidylethanolamine in the ratio 13:4 (w/w), the negatively charged liposomes contained phosphatidic acid and phosphatidylcholine in the ratio 4:13 (w/w), and the neutral liposomes contained phosphatidylcholine only. Lipid films were deposited on the surfaces of glass vessels by evaporation, under a stream of N₂, of chloroform solutions containing 22.5 nmol of appropriate phospholipids. Then 15 ml of 100 mm-potassium succinate buffer, pH 6.4, containing 150 mm-KCl was added and sonicated under N₂ at room temperature for 10 min at 24 kHz.
LIPOSOMES AND ATP-ACTIVATED AMP DEAMINASE FROM HEART

with a 100 W MSE ultrasonic disintegrator. Before sonication the O₂ concentration of the sample was lowered by bubbling N₂ through the sample for 10 min. In this way the O₂ concentration reached about 0.010 mM as measured by a Clark-type oxygen electrode. Transparent and only faintly opalescent dispersions have been obtained by this procedure which consist of phospholipid-bilayer structures (Phillips, 1972).

Analytical procedures

NH₃ was measured by the phenol/hypochlorite method described by Chaney & Marbach (1962). Protein was determined either by the method of Lowry et al. (1951) or by the method of Warburg & Christian as described by Layne (1957). Phospholipid phosphorus after mineralization was determined as described by Gomori (1942).

Results

In contrast with AMP deaminase from skeletal muscle, which is sensitive to the ATP-activating effect only at low K⁺ concentration (Zielke & Suelter, 1971), the enzyme isolated from heart muscle is influenced by both ATP and ADP, even in the presence of 150 mM KCl (Figs. 2a and 2b). As Figs. 2(a) and 2(b) show, the velocity of the reaction increased in a sigmoidal fashion with increasing AMP concentration in the absence of ATP and ADP, both in the presence and absence of liposomes. Addition of ATP or ADP to the reaction mixtures shifted the kinetics from sigmoidal to hyperbolic, thereby lowering the apparent Kₘ (half-saturating substrate concentration) for AMP. This value changed from 5 mM to about 1.5 mM with the addition of 1 mM ATP or -ADP. The addition of liposomes did not influence the enzyme kinetics in the absence of ATP and ADP. However, in the presence of ATP, preincubation of the enzyme with liposomes caused a further shift of Kₘ to 0.5 mM and a 2-fold increase of Vₘₙₐₓ (Fig. 2a).

From the Hill equation:

\[ \log \left( \frac{v}{V_{\text{max.}} - v} \right) = h \log ([AMP]) - \log K \]

the h (Hill coefficient) value for the plots with AMP was 2.35. With the addition of ATP at 1 mM, the h value for the same plots was 1.55, and with the addition of ATP and liposomes it was 1.04. The addition of liposomes to the medium in the absence of ATP and ADP did not change the enzyme kinetics, the h value in this case being 2.41.

Liposomes without charge, positively charged liposomes and negatively charged liposomes all had a pronounced effect on the ATP-activated AMP deaminase (Table 1). None of the liposomes tested influenced the activity of AMP deaminase in the absence of ATP and ADP (Table 1). The effect of liposomes composed of phosphatidylcholine only (those with no charge) was greatest, and hence the detailed experiments were performed with these liposomes. As little as 75 nmol of phospholipid added in the form of liposomes had a considerable effect on the ATP-activated AMP deaminase activity (Fig. 3), and the effect increased with the increasing amount of liposomes added up to 300 nmol of phospholipid in the sample.

Although no information is available about the effect of orthophosphate on AMP deaminase from heart, this compound is known to exhibit a negative allosteric effect on AMP deaminase from skeletal muscle and brain (Zielke & Suelter, 1971). One could suspect that liposomes would affect not only the activating effect of ATP but also the inhibiting effect.

Discussion
The molecular nature of the observed effect of liposomes on the kinetics of heart AMP deaminase may only be the subject of speculation at present. If association of liposomes with the enzyme does occur, it cannot be very strong, since an attempt to separate the complex on Sepharose 4B or by centrifugation failed (results not shown). The mixture of liposomes and AMP deaminase was separated into two components, only one of which showed enzyme activity, the other containing the liposomes and no AMP deaminase activity. After separation from liposomes on Sepharose 4B, the enzyme again showed the same basal activity and was susceptible to the activating effect of both ATP and liposomes in the same way as before.

On addition of ATP and liposomes, the h value derived from the Hill plot decreased from 2.32 to about 1. The enzyme changes from a form that exhibits co-operative binding of AMP to a form that conforms to Michaelis–Menten kinetics. The h value of 2.35 may indicate a minimum of three co-operative binding sites for AMP (Cornish-Bowden, 1976), and is consistent with the proposed tetrameric structure of the enzyme from skeletal muscle (Coffee & Kofke, 1975; Boosman & Chilson, 1976). A similar shift in the h value of the Hill plots on addition of ATP alone has been observed with the enzyme from calf brain (Setlow & Lowenstein, 1967), rabbit skeletal muscle (Smiley & Suelter, 1967) and inverte-
brate muscle (Gibbs & Bishop, 1977). It is possible that ATP, while bound to both lipid layer and the heart AMP deaminase, exhibits its activating effect more efficiently.

One is tempted to suppose that an effect similar to that shown by liposomes may be displayed by natural phospholipid-containing membranes in the heart cell. It has been proposed by Berne (1964) that adenosine is a mediating factor in the autoregulation of the coronary blood flow in the heart. Adenosine is produced in the tissue by the action of 5'-nucleotidase on AMP, and hence the abundance or shortage of the last compound is a crucial regulatory factor of adenosine concentration in the tissue (Zydowo, 1976). AMP deaminase, if not inhibited, removes AMP from the adenine nucleotide pool, thus diminishing the concentration of the substrate for 5'-nucleotidase. High activity of AMP deaminase observed in the presence of ATP may occur in the tissue when O2 supply is sufficient and production of ATP in mitochondria exceeds its hydrolysis in the course of heart myosin adenosine triphosphatase activity. In this case, adenosine as a factor increasing O2 supply through an increased coronary blood flow is not required and AMP concentration should be kept low. If an excessive orthophosphate production from ATP is taking place as a result of predominance of myosin adenosine triphosphatase action over oxidative phosphorylation, AMP deaminase would be inhibited (Fig. 4), and enhanced adenosine production could occur. Burger & Lowenstein (1967) calculated from their experiments with heart extracts that the presence of ATP may cause a 5-fold increase of AMP deamination and a 10-fold decrease of adenosine production from AMP.

Supposing that natural membranes (e.g. mitochondrial membrane) would display effects on the kinetics of AMP deaminase similar to those shown by liposomes, one may suspect that the molecules of enzyme that are in close contact with the membrane would be even more susceptible to the changes of ATP concentration. This would speed up the functioning of the subtle interplay of several regulatory factors influencing the activity of AMP deaminase and hence the operation of the whole purine nucleotide cycle as well as adenosine production in the heart. The effect of liposomes described here is peculiar to AMP deaminase from heart, as we were unable to show this effect when using the enzyme from skeletal muscle both at high and low concentrations of K+. It is therefore even more tempting to suggest that the physiological significance of the effect of phospholipid-containing membranous structures on AMP deaminase is connected with the speeding up of the regulatory effects so important for heart function.
