The Formation and Distribution of Bilirubin Monoglucuronide and Diglucuronide in Rat Liver Slices

By MARY T. CAMPBELL and GEOFFREY J. DUTTON*
Department of Biochemistry, University of Dundee, Dundee DD1 4HN, Scotland, U.K.

(Received 6 November 1978)

1. Bilirubin conjugation in rat liver slices was reassessed by using analysis of ethyl anthranilate azopigments to estimate separately the formation of bilirubin mono- and di-glucuronides. 2. Conjugation in slices resembles the situation in vivo more closely than does microsomal conjugation, in that diglucuronide is formed in appreciable quantity. 3. Both bilirubin mono- and di-glucuronides were present in slices in approximately equal amounts, but the monoglucuronide was the major product found in the incubation medium. 4. These results are discussed in relation to recent theories on the relationship between bilirubin mono- and di-glucuronide formation in vivo.

In man and rat bilirubin is excreted in bile predominately as diconjugates of glucuronic acid (Feverly et al., 1972a, 1977a; Noir, 1976), but synthesis in vitro of bilirubin conjugates by using broken-cell preparations from human and Wistar rat liver, with UDP-glucuronic acid as sugar donor, predominantly produces bilirubin monoglucuronide (Van Roy & Heirwegh, 1968; Black et al., 1970; Feverly et al., 1972b), a presumed intermediate in formation of diglucuronide (Heirwegh et al., 1973). This reaction is catalysed by microsomal UDP-glucuronyltransferase (EC 2.4.1.17). Liver slices provide a practical, but little used, alternative for investigating the products of bilirubin conjugation in vitro. One report has suggested that rat liver slices produce only bilirubin diglucuronide (Schoenfield & Bollman, 1963), thus closely reflecting bilirubin conjugation in vivo, and cultures of hepatoma MH2C1 cells may also synthesize both mono- and di-glucuronides (Rugstad et al., 1970). Since these reports, more reliable techniques have become available for identification and assay of conjugated bilirubin pigments (see Heirwegh et al., 1974). We have reinvestigated formation of bilirubin mono- and di-conjugates in rat liver slices by using these methods and find that both types of conjugates are formed. Diconjugate, however, was found mainly within the slices and appeared to have been converted into monoconjugate during or after excretion from them.

Materials and Methods

Bilirubin, glucaro-1,4-lactone and bovine serum albumin (fraction V) were from Sigma Chemical Co.,

Vol. 179

Poole, Dorset, U.K., and silica-gel 60 precoated glass plates or plastic sheets were from E. Merck, Darmstadt, Germany. Fresh male serum was obtained from healthy human volunteers and frozen male and female serum was provided by the Department of Virology, Ninewells Hospital, Dundee. Rat serum was obtained by heart puncture under diethyl ether anaesthesia. Adult male Wistar R rats, fed ad libitum, were used throughout.

Preparation and incubation of liver slices

This was carried out as described by Lathe & Walker (1958), except that the incubation medium contained 2.2ml of the phosphate/bicarbonate solution, 0.3ml of whole serum or bovine serum albumin solution (final albumin concentration approx. 0.12mm) and 30μl of bilirubin solution (final concentration 0.21mm). Each incubation flask contained two or three liver slices [total 200± 20 (mean ± s.d.)mg wet wt./flask] and control flasks were either incubated at 37°C without bilirubin, which was added at the end of incubation, or kept on ice with bilirubin added. Incubation began within 30min of the death of the animals and all experiments with dissolved bilirubin were performed in dimmed light.

After incubation, the flasks were chilled on ice and the contents homogenized. In experiments requiring separation of slices and medium the contents of the flasks were centrifuged at 600g for 2min, the supernatant (incubation medium) was removed and the slices were homogenized in 2.5ml of phosphate/bicarbonate solution.

Identification and quantification of bilirubin conjugates

Bilirubin conjugates were detected by formation of ethyl anthranilate azopigments at pH2.7 and
separated by t.l.c. (see Heirwegh et al., 1974). To 1 ml of sample was added 5 ml of glycine/HCl buffer, pH 2.7, and 2.5 ml of ethyl anthranilate reagent (Heirwegh et al., 1974). After 45 min at room temperature (18–20°C) the azopigments were extracted twice into a total of 4 ml of pentan-2-one, concentrated to a convenient volume by repeated washing with glycine/HCl buffer, and the \( A_{440} \) was determined. Azopigment formation was maximal under these conditions.

Bilirubin mono- and di-conjugate formation was estimated from the relative amounts of \( \alpha_0 \) (unconjugated azodipyrrole), \( \delta \) (azodipyrrole glucuronoside) and \( \alpha_3 \) (azodipyrrole glucoside) pigments. These were separated and identified by t.l.c. on silica-gel 60 plates with benzene/ethyl acetate (85:15, v/v) and then chloroform/methanol/water (65:25:3, by vol.) as solvent systems. Reference pigments were (a) diazotized rat bile and (b) authentic \( \delta \) and \( \alpha_3 \) azopigments, obtained by incubation of bilirubin with rat liver microsomal preparations and UDP-glucuronic acid or UDP-glucose respectively.

The separated azopigments were eluted completely from the silica with 2 ml of dimethylformamide/pentan-2-one (1:1, v/v) and 1 ml of water, the organic phase containing the pigments was separated by addition of 5 ml of glycine/HCl buffer, and the \( A_{440} \) was determined.

Incubated samples produced mainly \( \alpha_0 \) and \( \delta \) azopigments (see the Results section). Although only conjugated bilirubin should be diazotized at pH 2.7 (Van Roy & Heirwegh, 1968), controls containing high concentrations of unconjugated bilirubin yielded some \( \alpha_0 \) azopigment (see also Ostrow & Boonyapisit, 1978). Attempts to decrease this blank value by pre-extraction with chloroform were unsuccessful. Blank values were therefore subtracted and the amount of monoconjugated bilirubin estimated as equivalent to 2\( \alpha_0 \), the amount of diconjugated bilirubin being equivalent to the total azopigment formation minus 2\( \alpha_0 \). This method for measuring monoconjugate formation has been extensively discussed (Heirwegh et al., 1974; Fevery et al., 1977a,b).

Bilirubin monoglucuronide and diglucuronide preparations

These were obtained by extraction from Wistar rat bile collected under anaesthesia by catheterization of the common bile duct. The tetapyrroles were extracted into chloroform at pH 1.8 (J. Fevery, personal communication) and separated by t.l.c. on silica-gel 60 plates with chloroform/methanol/water (30:15:2, by vol.) as developing solvent. They were eluted with methanol, rapidly dried by rotary evaporation and redissolved in water for immediate use. The conjugates were identified from their azopigments, the bilirubin monoglucuronide preparation producing 54\% \( \alpha_0 \) and 46\% \( \delta \) azopigments, the bilirubin diglucuronide preparation 7\% \( \alpha_0 \) and 93\% \( \delta \) azopigments.

Preparation of cell fractions derived from smooth and rough endoplasmic reticulum

These preparations were obtained from rat liver by the discontinuous sucrose gradient method of Dallner (1974), the concentration ratio of RNA/protein being used to check their identity. Ratios were determined as 0.036 and 0.044 for two preparations derived from smooth endoplasmic reticulum and 0.24 and 0.26 for those derived from rough endoplasmic reticulum (Dallner, 1974). RNA was determined by the method of Wool & Cavicchi (1967) and protein by the method of Lowry et al. (1951) with bovine serum albumin as standard.

Assay of bilirubin-UDP-glucuronosyltransferase

This was assayed in digitonin-activated microsomal preparations by the method of Heirwegh et al. (1972).

Results

Formation of monoconjugates of bilirubin by rat liver microsomal preparations

Preliminary experiments confirmed that microsomal preparations from livers of Wistar rats in our colony produced almost exclusively bilirubin monoglucuronide. When digitonin-activated preparations, derived from either smooth or rough endoplasmic reticulum, were assayed for bilirubin-UDP-glucuronosyltransferase activity, the bilirubin conjugates yielded only \( \alpha_0 \) and \( \delta \) azopigments in approximately equal amounts. In two experiments, monoglucuronide produced was 91 and 87\% of total conjugate with smooth microsomal preparations and 94 and 91\% with rough microsomal preparations. These findings do not support previous suggestions that diglucuronides are formed primarily by microsomal fractions derived from rough endoplasmic reticulum (Halac et al., 1972).

Formation of monoconjugates and diconjugates of bilirubin by rat liver slices

(a) Formation of total conjugate. Adult rat liver slices conjugated bilirubin at a linear rate over a 2h incubation period (Fig. 1). Conjugation in the presence of male human serum was consistently higher [89.9 ± 7.3 (mean ± s.d.) nmol of conjugate formed/h per g of liver, \( n = 23 \)] than with female human or male rat serum or bovine serum albumin. With constant serum concentrations and variable bilirubin concentrations, conjugate formation was only detected when the molar ratio of bilirubin/albumin was greater than 0.3, thereafter increasing with increasing bilirubin concentrations (Fig. 2). Without serum albumin, bilirubin tended to precipi.
Liver slices (200 ± 20 mg wet wt.) were incubated with bilirubin (0.25 mM) and male human serum (350 µl/flask) as described in the Materials and Methods section for the times shown; total conjugate formation in slice and medium was measured (●). In another series of experiments, slices were separated from the medium after incubation and the bilirubin conjugates in slices (●) and in medium (△) were determined, the range shown being the S.E.M. for four samples.

The distribution of the two conjugates between tissue and medium after incubation is given in Table 1 for several experimental conditions. Approximately equal amounts of mono- and di-glucuronides were found within the liver slice, but the incubation medium contained 70–100% monoconjugates. This distribution was the same after 1 and 2 h incubations. The low amount of diconjugate in the medium was highest when the contribution of α3 azopigments was highest.

In spite of an apparently decreased excretion of diconjugates into the medium, they did not accumulate within the slice, suggesting their hydrolysis might be occurring either in the medium or in transit from the cell. However, glucaro-1,4-lactone, a specific inhibitor of β-glucuronidase, did not increase the proportion of diconjugate (Table 1). The possibility of hydrolysis was therefore tested more directly. Authentic bilirubin diglucuronide (see the Materials and Methods section) was incubated in the liver slice system, instead of bilirubin, with the appropriate controls. After 60 min incubation 75% of the total pigment was recoverable, but half of this was now detected as monoglucuronide, strongly suggesting that part of any diglucuronide synthesized during the original slice incubations had also been converted into monoglucuronide. This transforma-
Table 1. Percentage distribution of bilirubin mono- and di-conjugates between slice and incubation medium
Liver slices were incubated with bilirubin for the times given and the presence of bilirubin mono- and di-conjugates in slice and incubation medium was determined as described in the Materials and Methods section. Results are given as mean percentage of total conjugate formed ± S.E.M. for four samples in Expts. 1 and 2, and three samples in Expt. 3.

Discussion

Glucuronidation of bilirubin by rat liver slices should largely reflect its overall conjugation in vivo, a function of several processes: uptake of bilirubin from serum albumin, conjugation with glucuronic acid by microsomal UDP-glucuronosyltransferase, transport of conjugates to bile canalicular membranes and excretion across these membranes (see Fleischer & Arias, 1970). Formation of diglucuronides is arguably the least understood of these processes.

Our overall rates of conjugation in liver slices are comparable with those of Lathe & Walker (1958), but much lower (5% or less) than rates with fully activated UDP-glucuronosyltransferase assayed in cell extracts (Heirwegh et al., 1972; M. T. Campbell, unpublished work) or than maximum excretion rates in vivo (Van Damme & Desmet, 1969). A similar wide discrepancy between rates of bilirubin conjugation in slices and homogenates was observed by Lathe & Walker (1958). In spite of the high extracellular concentration of bilirubin and the high molar ratio of bilirubin to albumin, saturating concentrations were not reached intracellularly (Fig. 2), indicating that uptake of bilirubin is probably rate limiting; high concentrations of bilirubin may also be toxic to slices. The approximately equal distribution of total conjugated bilirubin between slices and medium at 1 and 2h (Fig. 1) indicates that excretion is not limiting here. This excretion may, however, be due to 'leakage' of conjugates across plasma membranes as well as to normal transit across bile canalicular membranes, such a 'leakage' being observed in vivo during infusion of rats with high bilirubin concentrations (Arias et al., 1961; Snyder et al., 1967).

The high proportion of monoconjugates formed by the liver slice system reflects the excess of mono-conjugate found in the medium and seems to have been due, at least partly, to conversion of diconjugates into monoconjugates, presumably in the medium or at the cell surface. The approximately equal amount of mono- and di-conjugates within the slice may reflect more closely the immediate intracellular products. Preliminary work suggests that in hepatocyte suspensions, also, diconjugates occur mainly within cells and not medium (M. T. Campbell, unpublished work). If we allow for some likely selective loss of diconjugate within the slice, either by the mechanism responsible for this loss in the medium or because of the demonstrated less complete extraction of diglucuronide than of monoglucuronide, then the proportion of diconjugate initially formed in our slices reaches the 60-75% normally excreted in Wistar rat bile (e.g. Fevery et al., 1972a; Noir, 1976; Jansen et al., 1977).

The presence of diglucuronide within liver slices is also interesting because of recent suggestions that it is formed in rat at the bile canalicular membrane by transesterification between two molecules of bilirubin monoglucuronide, possibly as the conjugate is excreted from the cell (Jansen et al., 1977; Wolkoff et al., 1978). By this theory monoglucuronide, but not diglucuronide, should be found within the hepatocyte (Wolkoff et al., 1978). In our experiments diglucuronide may be formed at the bile canalicular membrane, but, unlike the situation in vivo, may not
be excreted from slices by the canalicular mechanism: it may accumulate and be de-esterified as it ‘leaks’ across plasma membranes. Diglucuronide formation and transport of conjugates across canalicular membranes are separable events, since many species excrete predominately monoconjugates (Fevery et al., 1977a) and in man and rat the biliary monoconjugate/diconjugate ratio is altered drastically under a variety of conditions (Fevery et al., 1972b, 1977b; Noir, 1976). However, our results also suggest that diglucuronide is indeed formed at the canalicular membrane, but in the neighbourhood of high concentrations of bilirubin (i.e. at the periphery of the slice) a reversal of the reaction described by Jansen et al. (1977) occurs, so that diglucuronide and unconjugated bilirubin react there to form two molecules of monoconjugate. Such a reversal could explain the higher proportion of monoconjugate excreted in rats loaded with bilirubin (Fevery et al., 1972a; Noir, 1976) and would ensure the maximum efficiency of bilirubin excretion desirable in such circumstances and not otherwise explicable by the reaction of Jansen et al. (1977).

The authors thank Dr. S. Scott, Department of Virology, Ninewells Hospital, for providing human sera, Mrs. A. Donald for skilled technical assistance and the Scottish Hospitals Endowment Research Trust for financial assistance.
