(Received 17 August 1981/Accepted 13 November 1981)

1. The metabolism of hepatic glycogen, labelled with [6-3H]glucose at day 19.5 of gestation and with 14C from [U-14C]galactose at delivery, was followed for 10h in food-deprived gsd/gsd and control (GSD/GSD) neonatal rats. In the affected pups glycogen was maintained at 12% (w/w) and there was no loss of incorporated radioactivity. 3. The 3H and 14C in glycogen from the controls were both decreased by 80%, but 14C was removed at 0–5h and [6-3H]glucose at 5–10h. 4. Blood glucose concentrations in the unaffected neonatal rats fell from 5.3 mm at 20min to 1.7 mm after 10h. In the gsd/gsd pups blood glucose concentration was decreased from 2 mm at birth to 0.3 mm at 2.5 h: it was maintained at 0.8 mm between 5 and 10h. In neonatal rats that had been dead for 10h, hepatic glycogen was decreased by 34% in the controls and by 22% in the gsd/gsd pups. These results demonstrate that liver from the affected rats contains glycogenolytic activity, but that it is not expressed in living tissue.

Glycogen reserves in hepatic tissue of the developing rat foetus are laid down during the last quarter of gestation (Shelley, 1961). The rapid accumulation of this carbohydrate from day 18 to day 21 coincides, not only with an increase in the total and the active form of glycogen synthase (EC 2.4.1.11), but also with an increase in total glycogen phosphorylase (EC 2.4.1.1) (Devos & Hers, 1974; Watts & Gain, 1976; Bashan et al., 1979). At birth there is a rapid mobilization of liver glycogen: it is presumed that this serves to prevent hypoglycaemia until suckling and the onset of gluconeogenesis in the neonatal liver (Dawkins, 1963; Snell & Walker, 1973; Devos & Hers, 1974). During this period, as with the last 3 days of gestation, there are no substantial changes in the activities of either glycogen phosphorylase a or glycogen synthase a (Watts & Gain, 1976). This suggests that a futile cycle between glucose 1-phosphate and glycogen might occur in the liver of the late-term foetus and the neonatal rat pup. Indirect evidence for the occurrence of this cycle in hepatic tissue from the foetal rat has been presented by Goldwater & Stetten (1947), Watts & Gain (1976) and Gilbert & Bourbon (1978). It should be noted, however, that Devos & Hers (1974) have demonstrated that rodent glycogen phosphorylase is activated by anaesthesia and by stress. They have also shown that there was no detectable loss of 3H from glycogen, prelabelled with [6-3H]glucose at day 19.5 of gestation, until after parturition (Devos & Hers, 1974, 1980a). These workers have concluded that glycogen phosphorylase a activity is not expressed in the foetal rat liver.

In addition to the phosphorolytic degradation of glycogen, hepatic tissue from most animals contains a second glycogenolytic mechanism. This is lysosomal and involves the hydrolytic enzyme acid a-glucosidase (EC 3.2.1.20) (Lejeune et al., 1963). A deficiency of this enzyme results in a very severe form of glycogen-storage disease, Pompe's disease, which is characterized by the accumulation of glycogen within autophagic vacuoles (Hers & de Barys, 1973). Similar structures have also been observed in liver from neonatal mice (Jezequel et al., 1965) and rats (Phillips et al., 1967). More recent investigations have indicated that these vacuoles, glycogenosomes, might play a major role in glycogen mobilization in the neonatal rodent liver (Devos & Hers, 1980a; Iwamasa et al., 1980).

We have previously described an inbred strain of rat with a non-lethal form of glycogen-storage disease (Clark et al., 1980; Malthus et al., 1980). The defect in this rat, a deficiency of hepatic phosphorylase b kinase (EC 2.7.1.38), is transmitted as Mendelian autosomal recessive (Malthus et al., 1980). The lack of this enzyme prevents the degradation of the large glycogen reserves even during extended periods of food deprivation (Clark et al., 1980; Malthus et al., 1980). Comparative investigations of glycogen metabolism in liver from...
pre-term and post-term phosphorylase kinase-deficient (gsd/gsd) and control (GSD/GSD) rat pups should indicate the role of both phosphorylase a and α-glucosidase in the perinatal metabolism of this polysaccharide.

Materials and methods

Radiochemicals

[6-3H]Glucose and [U-14C]galactose were purchased from The Radiochemical Centre, Amersham, Bucks., U.K.

Enzymes

Amyloglucosidase, from Rhisopus, was obtained from Sigma Chemical Co., St. Louis, MO, U.S.A. Glucose oxidase and peroxidase were procured, as a commercial kit, from Boehringer Mannheim Pty. Ltd., Mount Waverley, Vic., Australia. Lactate dehydrogenase was from the same source.

Animals

The animals used in this investigation are inbred substrains of the NZR/Gd line (Goodall et al., 1975; Malthus & Clark, 1977). The mutation responsible for the rodent glycogen-storage disease has been designated gsd (Clark et al., 1980). As this condition is transmitted as an autosomal recessive trait, affected animals are designated gsd/gsd. Unaffected littermates, with normal glycogen concentrations after food deprivation, have been inbred for over 4 years without producing any affected (gsd/gsd) offspring. By convention these animals are designated GSD/GSD. The two strains of rats (gsd/gsd and GSD/GSD) were maintained in caesarian-originated specific-pathogen-free colonies at the Division of Human Nutrition and fed on a standard diet ad libitum.

Handling of animals

Female rats (200–250g body wt.) either gsd/gsd or GSD/GSD were caged with the appropriate bucks on the same night (3:00 p.m. to 9:00 a.m.) each week. The pregnant does (seven gsd/gsd and seven GSD/GSD) received two subcutaneous injections (0.3 ml each) of trace amounts of [6-3H]glucose (10μCi each) at a 1 h interval on day 19.5 of gestation (Devos & Hers, 1974), and the foetuses were delivered by caesarian section under ether anaesthesia at term (day 22). The neonatal rats that were not used immediately received a single intraperitoneal injection (5μl) of [U-14C]galactose (1μCi) and were placed in a humid atmosphere at 37°C. At the appropriate time intervals the pups were weighed, then killed by decapitation, and blood (50μl) was collected from the neck and deproteinized with 0.45 ml of 95% (v/v) ethanol. The livers of the neonatal rats were rapidly removed, blotted dry, and placed in tared tubes containing 3.0 ml of 30% (w/v) KOH and digested at 90°C for 3 h. Two portions of maternal liver (0.7–1.0 g) were excised and treated as described above. Maternal blood was drawn by puncture of the descending aorta, and 0.5 ml was deproteinized with 4.5 ml of 95% ethanol.

Isolation of glycogen

Glycogen was isolated from the KOH digest by precipitation with 80% ethanol. The pellet was dissolved in 4.5 ml of water, neutralized with 1 M H2SO4 and the glycogen reprecipitated in the presence of 65% ethanol for 12 h at 4°C. The pellet was finally dissolved in 5.0 ml of water.

Analytical procedures

Glucose in the deproteinized blood and that liberated by amyloglucosidase treatment of the purified hepatic glycogen was measured by using a glucose oxidase method (Clark et al., 1974). L(+)-Lactate in blood was determined enzymically by the method of Hohorst (1963). Radioactivity in liver glycogen and in foetal and maternal blood was assayed in a Triton-based liquid-scintillation 'cocktail' (Philippidis et al., 1972).

Column chromatography

Supernatant from the deproteinized blood was passed through three ion-exchange columns: Amberlite CG-120, Dowex 1 (acetate form) and Dowex 1 (borate form). Water, glucose, lactate, pyruvate and amino acids were eluted as described previously (Katz & Wals, 1972; Clark et al., 1975).

Statistical methods

The statistical significance of differences between experimental groups was determined by the analysis of variance (Brownlee, 1949). A $P$ value of 0.05 or less was taken as the criterion of statistical significance.

The statistical significance of differences between the rates of degradation of 14C-labelled, 3H-labelled and total glycogen were determined by performing a linear regression on the appropriate data for each separate litter. These results were converted into rates of glycogen utilization and were compared by the Kruskal–Wallis non-parametric analysis of variance (Kruskal & Wallis, 1952, 1953).

Results and discussion

The mean birth weight of the caesarian-delivered gsd/gsd pups that were killed immediately (4.98 ± 0.10 g; $n = 18$) was not statistically different from that of the controls (4.79 ± 0.095 g; $n = 17$). The unaffected animals remained at 4.8 g, but the weight of the gsd/gsd neonatal rats was decreased by 9% ($P < 0.05$) after 10 h of food deprivation. This loss was not reflected in the livers of these pups, which
remained at 310 mg (Table 1). On the other hand, the weight of hepatic tissue from the control neonatal rats was decreased by 40% at 10 h ($P < 0.001$; Table 1). The differences in liver weight between the gsd/gsd and control neonatal rats can be attributed to the glycogen content: this was unchanged in the affected pups, but was decreased by over 90% in the controls (Table 1; see also den Otter & Van Boxtel, 1971; Watts & Gain, 1976).

**Glycogen degradation in the neonatal liver**

In these experiments liver glycogen was labelled with [6-3H]glucose 2.5 days before birth and with 14C from [U-14C]galactose immediately after delivery (see the Materials and methods section). In the affected pups 3H in liver glycogen was not altered during the 10 h of food deprivation. Similar results were obtained when 14C radioactivity was monitored in the same samples (Table 1). In this case the isotope was maintained in the neonatal hepatic glycogen, at the 20 min value, throughout the investigation. These isotopic data demonstrate that the hepatic glycogen in the gsd/gsd neonatal rat cannot be mobilized either at birth or in the first 10 h after birth. This confirms the analytical data (Table 1), which demonstrate that the polysaccharide is maintained at about 670 μmol of glycogen glucose/g of liver (12% w/w) during the first 10 h post partum.

In the control pups the incorporation of [6-3H]glucose into hepatic glycogen was less than one-half that of the gsd/gsd neonatal rats (Table 1). Possible reasons for this difference are presented below in the Discussion section. The [6-3H]glucose, which had been administered to the mothers 2.5 days previously, was maintained in the liver glycogen of the control neonatal rats at the zero-time value for 5 h, but was then decreased by over 80% during the second 5 h of starvation (Table 1). The second isotope in this polysaccharide, 14C from [U-14C]galactose, was decreased by nearly the same amount (83%), but in this case it was within the first 5 h after birth (Table 1). Neither of these patterns of polysaccharide metabolism agree with the analytical determinations; these showed that the glycogen was degraded in a nearly linear manner from 9% (w/w) at birth to 0.8% (w/w) 10 h later (Table 1). Non-parametric analysis of variance of the rates of glycogen utilization during the first 5 h of food deprivation demonstrated that the rate of breakdown of total glycogen was significantly different from that of 3H-labelled glycogen ($P < 0.01$) and that of 14C-labelled glycogen ($P < 0.01$).

In control neonatal rats that were killed immediately after birth and placed in an incubator at 37°C there was a 29% decrease in hepatic glycogen after 1 h and a 34% decrease after 10 h (Table 1). The polysaccharide was also degraded in the dead gsd/gsd neonatal rats; in this case glycogen was decreased by 12% at 1 h and by 22% after 10 h (Table 1). Although the decreases in liver glycogen in neonatal rats that had been dead for 10 h were highly significant statistically ($P < 0.001$) the 3H content of the polysaccharide was not significantly diminished (Table 1). Very similar changes are obtained when these analytical results are compared by the paired Student's $t$ test. In this case hepatic glycogen was decreased by 21% ($P < 0.001$; $n = 5$) in the affected neonatal rats and by 35% ($P < 0.001$; $n = 6$) in the controls. Although this method of statistical analysis also demonstrated that there was no significant change in the 3H-labelled glycogen in the dead control neonatal rats, it revealed that the labelled polysaccharide was decreased by 12.5% ($P < 0.05$) in the gsd/gsd pups 10 h after death.

These results on glycogen catabolism in the neonatal rodent liver (Table 1) suggest that glycogenolysis proceeds in an ordered or sequential manner in the live and dead GSD/GSD neonatal rats. This pattern of metabolism is indicative of phosphorolysis (Devos & Hers, 1979). There is no evidence of glycogen degradation in liver from the live gsd/gsd neonatal rats (Table 1), but the random pattern of glycogenolysis post mortem (see above) suggests that a hydrolytic mechanism [possibly a-glucosidase (Lejeune et al., 1963) or a-amylase (Rutter et al., 1961)] is present in the hepatic tissue of these neonatal animals (Devos & Hers, 1980a).

**Metabolism of blood glucose and lactate**

In addition to comparing the metabolism of hepatic glycogen in the newborn gsd/gsd and GSD/GSD rat pups, these studies were extended to encompass the fate of glucose, lactate, 14C label and 3H label in the neonatal blood during the first 10 h of life (Table 2). The concentration of 3H label, from [6-3H]glucose, in blood from the gsd/gsd neonatal rats was over 15% higher ($P < 0.01$) than that of the control pups (Table 2). The radioisotope label remained at this concentration throughout the 10 h of food deprivation in the affected neonatal rats, but in the control pups it was significantly increased by 11% ($P < 0.001$) at 10 h (Table 1). This increase in 3H label concentration in blood in the control animals coincides with the marked decrease in 3H label in liver glycogen during the second 5 h of food deprivation (Table 1). Column chromatography of the ethanolic blood supernatants from both the affected and control neonatal rats revealed that only the 10 h sample from the control neonatal animals had appreciable amounts of 3H in the glucose fraction; this accounted for 5–7% of the total blood 3H. In the other supernatants most of the 3H label (95–97%) was eluted in the 3H2O fraction, and only 2–3% was present in the glucose fraction.

The data in Table 2 indicate that the half-life of 14C label from [U-14C]galactose in blood from the
Table 1. Effect of food deprivation on liver weight and the metabolism of liver glycogen in neonatal gsd/gsd and control (GSD/GSD) neonatal rats

Hepatic glycogen, labelled with [6-3H]glucose at 19.5 days of gestation and 14C from [U-14C]galactose after birth (Devos & Hers, 1974), was isolated and assayed as described in the Materials and methods section. Values are the means ± s.e.m. for the numbers of observations given in parentheses (means ± s.d. for two observations). *P < 0.05, **P < 0.01, and ***P < 0.001 for gsd/gsd versus control or for zero time versus other time intervals; N.S., not significant.

Table 2. $^{14}$C label, $^{3}$H label, glucose and lactate in blood from neonatal gsd/gsd and control (GSD/GSD) rat pups during 10 h of food deprivation

Foetuses were delivered at term by caesarian section of ether-anesthetized gsd/gsd or control (GSD/GSD) does and placed in an incubator at 37°C. At the appropriate time intervals the neonatal rats were weighed and decapitated, and blood was collected at the neck. Measurements were made as described in the Materials and methods section. Values are the means ± S.E.M. for the numbers of observations given in parentheses (means ± S.D. for two observations). *$P < 0.05$, **$P < 0.01$, and ***$P < 0.001$ for gsd/gsd versus GSD/GSD or for zero time versus other time intervals; N.S., not significant.

Vol 202
gsd/gsd neonatal rats is less than that in blood from the GSD/GSD pups. At the 60min and 150min samplings the concentration of 14C label in blood from the controls was significantly higher (P < 0.05) than that from the affected pups (Table 2). This probably results from the release of [U-14C]glucose from liver glycogen, as glycogenolysis occurs only in the control neonatal rats (Table 1). The half-life of [U-14C]glucose in rat blood is about 4 times that of [U-14C]galactose (Devos & Hers, 1979), and this would tend to elevate the concentrations of 14C label in the blood from the GSD/GSD pups at 60 and 150min. In the final blood sample (10h) concentrations of 14C label were nearly identical for both strains of rats (Table 2).

Previous work has demonstrated that the blood glucose concentrations in gsd/gsd rats fed ad libitum can be significantly lower than those of control (GSD/GSD) rats, but this difference is not increased during extended periods of food deprivation (Clark et al., 1980; Malthus et al., 1980). In the control neonatal rats, blood glucose concentrations at birth were significantly lower (P < 0.001) than those of their mothers, but they rose to the maternal value within 20min of delivery (Table 2). In the subsequent samples (60 and 150min) the concentration of the hexose was decreased by about 50%, and after 10h of food deprivation it was further diminished to less than 2mM (Table 2). The gsd/gsd neonatal rats were hypoglycaemic throughout the course of the investigation (Table 2). At delivery the concentration of glucose in their blood was about one-half that of the controls, and it was decreased by 80% within 60min. A nadir of less than 0.3mM was observed at 150min, but the glucose concentrations were increased more than 2.5-fold during the final 5h of food deprivation (Table 2).

Gain et al. (1980) have shown that the concentrations of glucose in blood from the gsd/gsd rat foetuses at days 17, 19 and 22 of gestation (2.7, 1.7 and 1.9mM respectively) were 30–65% (P < 0.005) lower than those from the control pups. It was further demonstrated the concentration of the hexose in the maternal gsd/gsd rats was also decreased by 35–50% (P < 0.005) over the same period of gestation. At day 19 the concentration of glucose in the gsd/gsd does was 3.98 ± 0.09mM (n = 10), whereas that in the controls was 5.99 ± 0.22mM (n = 8) (Gain et al., 1980). If this were also true in the present investigation, then the specific radioactivity of [6-3H]glucose in the foetal gsd/gsd rats would be 50% greater than that from the controls. This would explain, at least in part, why the incorporation of [6-3H]glucose into the hepatic glycogen of the affected neonatal rats at day 19.5 was more than double that found in the controls (Table 1).

Another mechanism that could account for this would be the presence of more glycogen synthase a in the liver of the affected foetus at day 19 of gestation. Although total glycogen synthase activity (expressed as units/mg of protein) is similar in both gsd/gsd and control foetuses at this period of development, the active form of this enzyme is actually diminished in hepatic tissue from the affected foetuses (K. R. Gain & C. Watts, personal communication). It is apparent from these results that differences in hepatic glycogen synthase a are not responsible for the increased incorporation of [6-3H]glucose (Table 1). Another possible explanation is that the labelled glucose that was incorporated into the liver glycogen of the control foetuses might be released by phosphorolysis and further catabolized (Watts & Gain, 1976). As this polysaccharide is not degraded in either the neonatal (Table 1) or the mature gsd/gsd rat (Clark et al., 1980; Malthus et al., 1980), it is unlikely that this would occur in the affected foetus in the latter stages of prenatal development.

The changes in blood lactate concentrations during the 10h of starvation were similar in both the gsd/gsd and the GSD/GSD neonatal rats (Table 2). The lactate concentrations were greatly elevated after delivery, but were decreased by more than 50% within 1h. These results demonstrate that this compound is rapidly metabolized in these pups after birth, and this metabolism presumably has a sparing effect on blood glucose. This is not apparent in the affected neonatal rats, where the concentration of the hexose fell by 80% within 60min of birth (Table 2), but in the control pups there was no significant removal of glucose from the hepatic glycogen stores during this time (Table 1).

**Perinatal synthesis and degradation of hepatic glycogen**

There has been a resurgence of interest over the last 2 years on whether glycogen reserves are synthesized and degraded in an ordered or random manner (Devos & Hers, 1979, 1980a,b) and on the role of lysosomal α-glucosidase in the mobilization of this polysaccharide in the newborn rat (Hers & de Barsy, 1973; Devos & Hers, 1980a; Iwamasa et al., 1980). The results of the present investigation add further information to both these areas of research. The isotopic and analytical data obtained with glycogen from the liver of the control neonatal rats (Table 1) show that this polysaccharide, like that from adult mice and rats (Devos & Hers, 1979), was synthesized and degraded in an ordered (sequential) manner. Thus [6-3H]glucose, which was the first isotopic label incorporated into the foetal GSD/GSD glycogen, was the last out, whereas 14C label from [U-14C]galactose, the last in, was nearly completely removed within 5h of birth (Table 2).
These results contrast with those from a similar study by Devos & Hers (1980a); they found that the glycogen from their neonatal rat pups was degraded in a random, presumably lysosomal, manner. The only differences between the present study and that of Devos & Hers (1980a) were that the latter workers labelled foetal glycogen with [14C]glucose and they delivered their foetuses at day 21.5 of gestation from decapitated mothers (cf. the Materials and Methods section).

There is no evidence for either phosphorolytic or hydrolytic degradation of glycogen in hepatic tissue from live gsd/gsd neonatal rats (Table 1), but the results obtained with affected neonatal rats that had been dead for either 1 or 10 h (Table 1) demonstrate that liver from the affected animals does contain some enzymic mechanism for the degradation of hepatic glycogen. The nature of this mechanism remains to be elucidated.

We are indebted to Professor H. G. Hers and Dr. R. M. Smith for helpful comments and criticisms of this work, and to Dr. P. Baghurst for his help with the statistical analyses.
