Metabolites of procainamide and practolol inhibit complement components C3 and C4

Edith SIM, Lesley STANLEY, Edward W. GILL and Alison JONES

Drug-induced systemic lupus erythematous arises from toxic side-effects of administration of hydralazine, isoniazid, procainamide and practolol. Hydralazine and isoniazid are nucleophilic drugs and inhibit the covalent binding reaction of complement components, C3 and C4, an effect likely to lead to deposition of immune complexes (a feature of systemic lupus erythematous). Procainamide and practolol do not themselves inhibit C3 and C4. A range of metabolites and putative metabolites of procainamide and practolol were synthesized, and tested for their ability to inhibit the covalent binding reactions of C3 and C4. The highly nucleophilic hydroxylamine metabolite of procainamide was strongly inhibitory in both tests, as was a putative hydroxylamine metabolite of practolol. These studies indicate a potential role for the hydroxylamine metabolites in mediating the toxic side-effects of procainamide and practolol, and emphasize the need for adequate measurements of hydroxylamine metabolites in human tissue.

INTRODUCTION

Effects on the immune system have been implicated in a wide range of adverse reactions to drug therapy. Among such adverse reactions is the condition resembling systemic lupus erythematosus (SLE) which occurs on long-term treatment with hydralazine, a hypotensive, and isoniazid, which is used in treatment of tuberculosis (Harpey, 1973). Both hydralazine and isoniazid are highly nucleophilic monosubstituted hydrazines and both are metabolized by the polymorphic N-acetyl transferase enzyme of the liver (Weber & Hein, 1985). For drug-induced SLE occurring as a side-effect of therapy with hydralazine (Perry et al., 1970) and isoniazid (Godeau et al., 1974) patients who develop the condition are almost exclusively slow acetylators. This suggests that the toxic side-effects are mediated by the drugs themselves and not by metabolites.

It has been demonstrated that hydralazine and isoniazid, but not their acetylated metabolites, inhibit the classical-pathway complement protein C4 (Sim et al., 1984). C4, and the homologous complement protein C3, contain an activated thiol ester which, on activation of C3 and C4 by appropriate proteinases, becomes exposed and reacts rapidly with any nucleophile, including (a) OH or NH2 groups on the surface of complement-activating particles, (b) water, or (c) soluble nucleophilic compounds present in the environment (for review and discussion see Davies & Sim, 1981; Sim et al., 1981; Law, 1983). When the classical pathway of the complement system is activated by, e.g., immune complexes, component C4 (bound to the complexes) cleaves C4, and activated C4 may then bind covalently to the surface of immune complexes (as in a above) or may react with water. Only C4 bound to immune complexes participates in formation of the C42 enzyme, which activates C3 (for review see Reid, 1986). Strong nucleophiles present in solution may form a covalent bond with activated C3 or C4, thus reducing the amount of C3 or C4 which binds to the immune complex. Covalent binding of hydralazine to activated C4 (Sim & Law, 1985), and of other nucleophiles to activated C3, has been documented (Sim et al., 1981; Law, 1983).

C3 and C4 deposition is important in regulating clearance of immune complexes. C3 deposition promotes solubilization of immune complexes by disruption of the immune lattice (Takahashi & Takahashi, 1981), and also facilitates phagocytosis of complexes via macrophage C3 receptors (Fearon & Wong, 1983). SLE is regarded as a disorder of immune complex clearance (Schifferl & Peters, 1983) and individuals with deficiencies of the early complement components (C1, C4, C2) are at increased risk of developing idiopathic SLE (Thompson, 1987). It seems likely, therefore, that inhibition of C4 deposition by isoniazid and hydralazine may be an important factor in development of drug-induced SLE.

Procainamide is also associated with development of drug-induced SLE as a toxic side effect. It is an aromatic amine, but is not a strong nucleophile, and is not an effective inhibitor of C4 binding (Sim et al., 1984). Procainamide, an anti-arrhythmic drug, is also metabolized mainly by N-acetylation (Kark et al., 1983). Both fast and slow acetylators can develop drug-induced SLE as a result of procainamide therapy, but slow acetylators are more prone to the condition (Reidenberg, 1981). As an alternative to N-acetylation, N-oxidation of procainamide occurs (Uetrecht et al., 1984), forming a highly nucleophilic hydroxylamine metabolite of the drug.

Practolol, a cardio-selective β-blocker, has also been associated with a condition like SLE (Raftery & Denman, 1973), although it has a more severe adverse side-effect known as the oculomucocutaneous syndrome (Wright, 1975). Practolol is an N-acetylated aromatic amine. De-
acetylated and N-oxidized forms may also occur. We have investigated the effect of procainamide, practolol, and their chemically synthesized metabolites or putative metabolites on C3 and C4 deposition in tissue, to determine whether nucleophilic metabolites can inhibit the covalent binding of C3 or C4 in a manner similar to hydralazine and isoniazid.

MATERIALS AND METHODS

Proteins

C1 (the activated C1 component) was purified from pooled human serum as described by Sim (1981). Trypsin (treated with 1-1-tosylamido-2-phenylethylchloromethyl ketone, type XIII) was purchased from Sigma Chemical Co. (Poole, Dorset, U.K.). C3 and C4 were isolated from pooled human plasma using the method described by Sim et al. (1981) and Sim et al. (1986) respectively. C3 and C4 were radio labelled with 125I using Iodobeads (Pierce, IL, U.S.A.) as catalyst as described previously (Sim et al., 1985). C1 and trypsin were separately coupled to CNBr-activated Sepharose (Pharmacia) at pH 8.5 in sodium bicarbonate buffer according to the manufacturer’s instructions to give 300–750 μg of enzyme/ml of packed Sepharose.

Covalent binding of C3 or C4

Covalent binding of activated C3 or C4 can be studied conveniently using an activating enzyme (proteinase) bound to Sepharose. 125I-labelled C3 or C4 activated by the proteinase can then form ester bonds to OH groups on Sepharose (Sim et al., 1981, 1984). Sepharose–C1 or Sepharose–trypsin was used as the combined activating and binding surface for C4 and C3 respectively. Incubation of 125I-labelled C4 with Sepharose–C1 (30 min, 37 °C) was done as described previously (Sim et al., 1984). Binding of C3 was studied similarly, in that Sepharose–trypsin [100 μl of a 1:1 (v/v) slurry in 25 mm-potassium phosphate/140 mm-NaCl, pH 7.4 (phosphate-buffered saline)] was incubated at 25 °C for 1 h in a total volume of 250 μl of phosphate-buffered saline containing 1 μg of 125I-labelled C3 (5 × 10^6 c.p.m./μg), and with or without the test compounds. The reaction was stopped by addition of 100 μl of 0.2 M-Tris/HCl/2% (w/v) SDS/8 M-urea (pH 6.8) and of 200 μl of Sephadex G-25 [1:1 (v/v) slurry in phosphate-buffered saline] as ‘carrier’ resin for centrifugation. Duplicate 20 μl samples of the total mixture were removed for determination of radioactivity. The rest of the mixture was centrifuged (2 min, 14000 g) and samples of supernatant were retained to determine the percentage of radioactivity unbound. Pellets were washed twice with 1 ml of each of the following solutions to remove non-covalently bound material: 0.1% (w/v) Triton X-100 in water; 2 M-NaCl/10 mm-sodium acetate, pH 5.5; 0.2 M-Tris/HCl/2% (w/v) SDS, 8 M-urea, pH 8.8. The pellet was transferred to a clean tube for estimation of covalently bound radioactivity. In each experiment, 100% inhibition was determined in the presence of 40 mm-NH4OH which inhibits completely covalent binding of C3 and C4. All additions of potential inhibitors were made from stock solutions adjusted to pH 7.4 and freshly made up each day. In each experiment, the extent of inhibition was measured in triplicate for each concentration of inhibitor.

Synthesis of metabolites

N-Acetylpriocainamide. Procainamide base, obtained from the hydrochloride by treatment with NaOH solution and extraction into chloroform, was treated, in chloroform solution, with an excess of acetyl chloride, with cooling. The crystalline product was recrystallized from propan-2-ol, and its m.p. was confirmed as 187°C.

N-Hydroxyprocainamide (hydroxylamine procainamide). This was prepared using the method described by Uetrecht et al. (1984).

Desetylpractolol and N-hydroxy-desacetylpractolol (hydroxyamine practolol). 1-(4-Nitrophenoxy)-2,3-propylene oxide was treated with isopropylamine in aqueous ethanol to give N-isopropyl-2-hydroxy-3-(4-nitrophenox)propylamine (compound A). Compound A was reduced in ethanol containing one equivalent of HCl using 10% palladium charcoal and H2 at 101.325 kPa pressure to give desacetylpractolol hydrochloride (m.p. 170°C).

Compound A was reduced catalytically using 10% palladium charcoal poisoned with 0.1% triethylphosphite, according to the method described by Uetrecht et al. (1984). H2 (2 mol) was taken up and h.p.l.c. analysis of the product showed a single peak, well-resolved from the corresponding nitro and amino compounds. The product N-hydroxy-desacetylpractolol (hydroxyamine practolol) was isolated as the oxalate salt dihydrate (m.p. 190°C).

Structures of compounds discussed are shown in Figs. 1 and 3.

SDS/polyacrylamide-gel electrophoresis

Samples of the incubation supernatants of the pure radiolabelled proteins were subjected to SDS/polyacrylamide-gel electrophoresis after reduction and alkylation as described previously (Sim & Law, 1985) and then autoradiography of the dried gels was carried out (Sim et al., 1981).

RESULTS

Procainamide and metabolites

A scheme for the metabolism of procainamide and the structures of the compounds discussed is shown in Fig. 1. The logarithmic dose–response curve for the inhibition by procainamide and its hydroxylamine metabolite of 125I-labeled C3 binding to Sepharose–trypsin is shown in Fig. 2. The concentrations of compounds giving 50% inhibition of 125I-labelled C3 binding to Sepharose–trypsin and 125I-labelled C4 binding to Sepharose–C1 are shown in Table 1. For binding of both
Drug metabolites inhibit C3 and C4

![Inhibition of binding of 131I-labelled C3 to Sepharose-trypsin](image)

131I-labelled C3 (5 × 10^6 c.p.m.) was incubated with Sepharose-trypsin in the presence or absence of procainamide (●) or the hydroxylamine metabolite (○), and the amount of 131I-labelled C3 covalently bound was measured after washing, as described in the text. The extent of inhibition was determined from 100% inhibition obtained in the presence of 40 mM-NH₄OH. Results are shown as the average of triplicate determinations and error bars indicate the range of values observed.

**Practolol and metabolites**

A scheme for generation of the practolol metabolites which have been investigated is shown in Fig. 3. The

Vol. 251
effects of practolol and its putative metabolites on $^{125}$I-labelled C3 and $^{125}$I-labelled C4 binding are shown in Table 1. Again the hydroxylamine metabolite is a potent inhibitor of C3 and C4 covalent binding activity.

**DISCUSSION**

It has previously been suggested that toxic metabolites of procainamide (Uetrecht et al., 1984; Budinsky et al., 1987) and practolol (Amos et al., 1978) are generated by oxidation of these drugs. Our results show that the hydroxylamine derivatives of both drugs inhibit the covalent binding reaction of activated C4 and C3. Two other drugs, hydralazine and isoniazid, which are also associated with toxic side-effects giving rise to SLE-like symptoms, also inhibit C3 and C4 (Sim et al., 1984). As discussed in the Introduction, inhibition of C3 and C4 binding may diminish clearance of immune complexes. Thus inhibition of C3 and C4 by these drugs or their metabolites is likely to contribute to the immune complex deposition characteristic of SLE.

Hydroxylamine procainamide is a strong nucleophile and will react slowly with 'bystander' proteins, becoming covalently bound with low efficiency to, e.g., ovalbumin over a period of 14 h (Uetrecht, 1985). However the reaction described in the present study is likely to occur essentially instantaneously once C3 and C4 are activated (Sim et al., 1981).

At concentrations of 1–2 mM-hydroxylation procainamide or hydroxylamine practolol 50% inhibition of C3 and C4 binding occurs. Inhibition is detectable at much lower levels (Fig. 2). In a previous study, slightly lower concentrations of hydralazine and isoniazid were found to cause 50% inhibition of C4 binding. It is not possible to relate these concentrations of drugs or metabolites to concentrations found in tissues during therapy with any of the four drugs named above, as measurements of these substances in human tissues, have not adequately been made. Many measurements are available for procainamide and its major identified metabolites (N-acetylprocainamide and p-aminobenzoic acid) in body fluids and urine after short-term (1–4 days) administration of the drug. Patients receiving 1–1.5 g of procainamide/day attain a therapeutic plasma concentration of up to approx. 70 μM, with N-acetylprocainamide levels of up to 170 μM. Procainamide and the N-acetyl form equilibrate rapidly from the plasma into tissue fluids and both forms of the drug are excreted in the urine. SLE-like side effects occur, however, only after long-term therapy with procainamide (1–1.5 g/day for several years) (Reidenberg, 1981; Qazi & Gerber, 1986), and the pattern of tissue accumulation of the drug and its metabolites is unknown. The hydroxylamine metabolite discussed here has only recently been detected (Uetrecht et al., 1984; Uetrecht, 1985; Budinsky et al., 1987), and its quantitative importance as a metabolite is as yet unknown. We would suggest, however, that this metabolite is likely to be of major importance in inducing SLE symptoms.

The toxic effects of practolol are associated mainly with the eye, and work with single high-dose (400 mg/kg) administration of practolol to hamsters, has clearly shown that the drug and its metabolites accumulate in the eye up to a level of approx. 200 μM (Rosenbaum et al., 1986). In humans, long-term therapy with practolol may also result in accumulation of the drug and its metabolites in the eye. If the putative hydroxylamine metabolite accumulates in the eye, it may cause local inhibition of complement in the blood supply of the lacrimal glands, leading to deposition of immune complexes and reduction in tear section, as has been described in the oculomucocutaneous syndrome (Wright, 1975). Complement activity is also present in the cornea (Mondino & Brady, 1981) and lesions observed in this syndrome may also be associated with antibody deposition in the corneal/conjunctival area.

The authors thank the Wellcome Trust and Arthritis and Rheumatism Council for financial support and Michelle Wood for technical assistance. We also thank Bob Sim for his helpful comments on the manuscript.
