The aldolase concentration in sarcoplasm from foetal skeletal muscle is low, like that of adult heart muscle, although the enzymic activity rises as the foetus develops. The general conclusion of this comparison is that at least for the components moving towards the cathode foetal-muscle sarcoplasm is more comparable with that of adult heart muscle than that of white skeletal muscle. The sarcoplasm of red skeletal muscle appears to be intermediate between these two types. The high concentration of aldolase in the adult-skeletal-muscle sarcoplasm might be expected in view of the well-developed ability of this tissue to function anaerobically. These facts together with our findings suggest that after birth aldolase and other proteins of a high isoelectric point increase rapidly in amount in response to the increased activity of the skeletal muscle.

SUMMARY

1. Rabbit skeletal muscle has been fractionated by chromatography on diethylaminoethylcellulose at pH 7.6 and 9.3.
2. On starch-gel electrophoresis of adult-rabbit-skeletal muscle at least 15 migrating bands have been recognized and some of them identified with known proteins.
3. The more positively charged protein components which are readily eluted from diethylaminoethylcellulose are relatively much decreased in sarcoplasm isolated from foetal-rabbit skeletal muscle and from adult heart muscle compared with the amounts present in the corresponding fraction from adult skeletal muscle.
4. The level of aldolase activity in foetal-skeletal-muscle sarcoplasm is comparable with that in adult-heart-muscle sarcoplasm but much lower than that found in adult-rabbit-skeletal muscle sarcoplasm.

This work was done during the tenure of a Guinness Research Scholarship by one of us (D.J.H.). We are indebted to the National Science Foundation for a grant (NSF-G10933) which has defrayed in part the expenses incurred in this research. Our thanks are also due to Dr H. Feinberg and Dr D. G. Walker for help in the perfusion experiments.

Protein Synthesis in Mitochondria

3. THE CONTROLLED DISRUPTION AND SUBFRACTIONATION OF MITOCHONDRIA LABELLED IN VITRO WITH RADIOACTIVE VALINE*

By D. B. ROODY

National Institute for Medical Research, Mill Hill, London, N.W. 7

(Received 24 April 1962)

In previous publications from this Laboratory the conditions for incorporation of radioactive amino acids into the protein of isolated rat-liver mitochondria were examined (Reis, Coote & Work, 1959; Roody, Reis & Work, 1961a) and negligible rates of incorporation in vitro were reported for the soluble proteins in the mitochondrial fraction, including catalase, malic dehydrogenase and cytochrome * (Roody, Suttie & Work, 1962). The

chief site of incorporation was into material rich in RNA, phospholipid and succinoxidase that was not extracted by treatment with neutral detergents (Roodyn, 1961). In this paper the processes that occur during the fractionation and extraction of mitochondria by the action of detergents have been studied and the distribution of radioactive protein in the various subfractions so obtained has been determined. By suitable variation in the conditions, it has been possible to obtain controlled disruption of the mitochondria and to demonstrate that the major site of incorporation in vitro is into insoluble lipoproteins probably associated with the mitochondrial membrane.

METHODS

Preparation of mitochondrial subfractions

Mitochondria. These were prepared from rat liver in 0.3M-sucrose—2 mM-EDTA (disodium salt)—0.03M-nicotinamide, as described by Roodyn et al. (1961 a). They were subjected to subfractionation as follows.

Preliminary study of disruption with detergents (Figs. 1—4). Mitochondria were suspended in 0.3M-sucrose and rapidly mixed with a suitable volume of 8% (v/v) detergent in 0.3M-sucrose. The turbidity of the solution was immediately read in an EEL nephelometer, the instrument being set to 100 with a suspension of untreated mitochondria. In some experiments (Figs. 1 and 4) the degree of disruption was measured by immediately centrifuging the suspensions at 10 000g for 30 min. and analysing the sediment for protein or total N. To obtain satisfactory turbidity readings, the mitochondrial concentration used in these preliminary studies was less than that used in later experiments. Experiments in which turbidity was measured were carried out at room temperature. All others were carried out at 0°C.

Isolation of RNA—lipoprotein complex (Fig. 5). Mitochondria suspended in 0.3M sucrose were treated with increasing amounts of detergent (Fig. 5). After 10 min. at 0°C the suspension was centrifuged at 10 000g for 30 min. The pellet (fraction A) was buff-coloured in the centre, but was surrounded by a rim of reddish brown translucent material. The turbid supernatant was centrifuged at 105 000g for 60 min. and gave a reddish brown gel-like pellet (fraction B), which contained a small quantity of darker granules in the centre. The supernatant (fraction C) was optically clear and faint yellow in colour. For analysis, fractions A and B were resuspended in 0.3M-sucrose.

"Titration" with detergent (Figs. 6, 7 and 8). Portions (10 ml) of solutions of Triton X 100 in 0.3M sucrose were added to Spinco centrifuge tubes (capacity 12 ml.). A portion (2-0 ml.) of the mitochondrial suspension in 0.3M sucrose was blown into the detergent and the tubes were rapidly mixed and sealed. After the tubes had been centrifuged at 105 000g for 60 min., the pellets were resuspended in 0.3M-sucrose for analysis.

Preparation and subfractionation of crude RNA—lipoprotein complex (Tables 1, 2 and 5). The mitochondrial suspension, containing 150—200 mg. of protein, was incubated in 30 ml. of radioactive incubation medium, brought to 0°C and 1-0 ml. of carrier valine (10 mg./ml.) was added. The suspension was made up to 50-0 ml. with 0.3M-sucrose, 2-0 ml. of 8% (v/v) Triton X 100 in 0.3M-sucrose added, and the suspension was immediately centrifuged at 105 000g for 60 min. The resulting pellet was resuspended in either 50 ml. of 0-5% (v/v) Triton X 100 in 0.3M-sucrose or 50 ml. of 4-5% (v/v) Triton X 100 in 0.3M-sucrose (Table 1, Expts. 1 and 2) and left for 15 hr. at 0°C. The material was centrifuged again at 105 000g for 60 min. to give RNA-rich and lipid-rich components. Apart from chemical analysis, the sediment was not fractionated further. The supernatant was treated with 25 g. of ammonium sulphate/100 ml. (Table 2). A flocculent precipitate appeared that was separated by filtration. The filtrate gave no further precipitate on the addition of more ammonium sulphate and was rejected. The precipitate was washed off the filter paper with 10 ml. of water and treated with 2 ml. of butanol, added dropwise with constant stirring at 0°C. The turbid solution was centrifuged at 3000g for 15 min. and a buff-coloured layer of protein appeared at the interface of the aqueous and butanol-1-ol phases. It was carefully removed, resuspended in 10 ml. of water and treated with 2 ml. of butanol-1-ol a second time. The floating buff layer again appeared after centrifuging. It was removed and resuspended in 0.1M-potassium phosphate, pH 7-0, in which it appeared to be completely insoluble.

The lipid-rich component, prepared as described in Table 1, Expt. 1, was subfractionated on calcium phosphate (Table 5) as follows: the fraction, containing 10—15 mg. of protein in 40 ml. of 0.3M-sucrose—0-5% Triton X 100, was loaded directly on to a calcium phosphate column (2-5 cm. x 1-0 cm.). The column was washed with 20 ml. of 0-02M-potassium phosphate, pH 7-0, and then with 30 ml. of 1-0M buffer. Most of the coloured material on the column came off as a sharp band in the molar buffer and repeated washing with this buffer, or with 1-0M-potassium phosphate saturated with potassium chloride, failed to remove the remaining material attached to the column. The column was then suspended in 6—10 vol. of 1-0M-sodium citrate, pH 5-9, and left at 0°C overnight. The faintly turbid solution was then centrifuged at 3000g for 15 min. A clear band of lipoprotein rose to the top of the tube. Some flocculent material was present in the underlying solution and there was a small precipitate at the bottom of the tube. The floating layer was removed carefully, suspended in 0-2M-potassium phosphate, pH 7-0, and dialysed for 15 hr. against several changes of this buffer. It was then centrifuged at 105 000g for 60 min. and sedimented as a gel-like pellet.

The detergent-soluble proteins (Fig. 5, fraction C) were also submitted to this procedure (Table 6). The fraction containing 50—70 mg. of protein in 45 ml. of 0.3M-sucrose—0-2% Triton X 100 was loaded, without prior dialysis, on to a calcium phosphate column (8-0 cm. x 1-3 cm.) and treated exactly as described above. The fractionation appeared to be similar, except that a greater amount of protein passed through the column or was eluted with molar buffer. During elution with molar buffer an intense brownish yellow band with a sharp absorption peak at 410 mp came off the column. When the calcium phosphate, with its attached lipoprotein, was dissolved in sodium citrate and centrifuged, a thin layer of floating material was obtained but there was no sediment. The floating material sedimented as a gel-like pellet after dialysis and centrifuging at 105 000g.

Preparation of "structural protein" by method of Green,
Tisdale, Criddle, Chen & Bock (1961b) (Table 3). Mitochondria containing 150 mg. of protein were incubated with [14C]valine. Carrier valine was added and the mitochondria were sedimented at 10 000 g for 10 min. They were resuspended in 20 ml of detergent solution (0·25 M-sucrose—2% sodium deoxycholate—1% sodium cholate—0·75% sodium dodecyl sulphate). After 10 min. at 0°, the lyed mitochondria were centrifuged at 105 000 g for 60 min. A greenish brown sediment was obtained. A trace of sodium dithionate was added to the supernatant and solid ammonium sulphate added slowly to give 12% saturation. The copious white precipitate was sedimented at 3000 g for 15 min. and washed twice with 0·25 M-sucrose. It was suspended in 2 ml of 20% saturated ammonium sulphate solution containing 20 mg. of sodium deoxycholate; 2-0 ml of butan-1-ol was added dropwise and the material centrifuged at 3000 g for 10 min. A layer of protein appeared at the interface of the butan-1-ol and aqueous phases. It was removed, washed with 0·25 M-sucrose, suspended in 6-0 ml of 50% (v/v) methanol and heated at 50° for 30 sec. It was sedimented at 3000 g for 10 min. and heated once more in 50% methanol at 50° for 30 sec. The final sediment, which was a copious white precipitate, was taken as the 'structural protein'.

In the modification of the above method (Table 4) mitochondria containing 190 mg. of protein were disrupted with the cholate—deoxycholate—dodecyl sulphate mixture as described above. The sediment after 60 min. at 105 000 g was extracted a second time by suspending it in 10 ml. of the detergent solution and centrifuging at 105 000 g for 60 min. The supernatants from the two detergent treatments were then fractionated by the dropwise addition of increasing volumes of saturated ammonium sulphate. The precipitates were sedimented at 3000 g for 10 min. and assayed for radioactive protein without further washing.

**Incubation with radioactive amino acids.** Mitochondria were incubated for 90 min. at 30° under oxygen with 0-1 μc of universally labelled L-[14C]valine/ml as described by Roodyn et al. (1961 a, 'medium B'). The media were not supplemented with antibiotics in these experiments. The radioactive valine and the methods used for the isolation and counting of the radioactive protein were as described by Roodyn et al. (1962).

**Enzyme determinations.** Malic dehydrogenase was estimated spectrophotometrically at pH 9-9, as described by Roodyn et al. (1962). Succinoxidase was estimated manometrically by the method of Schneider & Potter (1943), except that aluminum trichloride was omitted from the reaction mixture.

**Chemical estimations**

Acid-soluble material, RNA, phospholipid and protein were separated and estimated as described by Roodyn et al. (1961 a). It was assumed that 1 mg. of phospholipid P was derived from 25 mg. of phospholipid. In certain fractions, the presence of detergent interfered with the quantitative precipitation of the protein and nucleic acid. Trichloroacetic acid (5%, w/v) caused 0-2% Triton X 100 to come out of solution and it then sedimented with the precipitated protein. It could then be readily removed by extraction with ethanol or acetone, but it is possible that when the ratio of detergent to protein was very high (cf. Tables 5 and 6, fraction C) protein was lost at this stage. The detergent is not thrown out of solution by 1-0 N-perchloric acid. However, preliminary experiments suggested that protein was not then fully precipitated. Attempts to remove the detergent by careful mixing with butan-1-ol, ether or chloroform were unsuccessful. Some improvement in the precipitation of protein from detergent solutions with 5% (w/v) trichloroacetic acid was obtained by heating the suspension at 90° for 30 min. (this could not be used if RNA analyses were required). Because of these difficulties in obtaining quantitative precipitation, the results below are usually expressed as 'relative concentration' (i.e. value/mg. of protein divided by value/mg. of protein in intact mitochondria), rather than as a percentage of the total amount. (This can readily be obtained by multiplying 'relative concentration' by percentage of total protein.) In addition the percentage recoveries are often low because, apart from the experiments illustrated in Figs. 1–5, the assays on the mitochondrial subfractions were done after incubation of the mitochondria, whereas the value for intact mitochondria was obtained with fresh material.

Breakdown of substances (e.g. RNA) during incubation would therefore give an apparently poor recovery. However, the poor recoveries of total protein and radioactivity in the more complex fractionations were undoubtedly due to failure to precipitate quantitatively from detergent solutions.

**Materials**

Calcium phosphate was prepared as follows: 100 ml. of water was stirred with a magnetic stirrer and 250 ml. of 0·5 M-calcium chloride and 250 ml. of 0·5 M-disodium hydrogen phosphate were slowly dripped in, the phosphate being run in at twice the rate of the calcium chloride. The precipitated calcium phosphate was washed several times with water and then with 0·02 M-sodium phosphate, pH 7·0. It was kept at 0° and used within 5 days of preparation.

Radioactive valine was obtained from The Radiochemical Centre, Amersham, Bucks. The Triton detergents were kindly supplied by Charles Lennig and Co. Ltd., Bedford Row, London, W.C. 1. Sodium dodecyl sulphate was a recrystallized sample kindly provided by Dr H. R. V. Arnstein.

**RESULTS**

**Study of factors influencing disruption of mitochondria by detergents**

Amongst several surface-active agents examined the neutral detergent Triton X 100 (one of the alklyphenoxy polyethoxyethanol series produced by Rohm and Haas Co., Philadelphia, Pa., U.S.A.) was found to be most effective on a weight basis. Most of the experiments described below were with this detergent.

When Triton X 100 is added in sufficient concentration to a suspension of mitochondria, an immediate visual clearing occurs that is coincident with a marked fall in turbidity and with the release of protein and nucleic acid from the mitochondria, as shown by analyses on the 10 000 g pellet (Fig. 1). If a sufficient concentration of detergent is used the fall in turbidity takes place in less than 5 sec., indicating an almost instantaneous lysis of the
mitochondria. With lower concentrations of detergent, however, this immediate rapid fall is followed by a slower fall lasting 40–50 min. (Fig. 2). This slower fall also coincided with the release of protein and nucleic acid from the 10 000g pellet, and was not simply due to swelling. For this reason, the time between addition of the detergent and separation of the mitochondrial subfractions was always kept to a minimum.

For a given concentration of detergent, the extent of disruption is also affected by the concentration of the mitochondrial suspension, the more dilute suspensions being more easily disrupted (Fig. 3). The degree of disruption is also affected by the length of the polyoxyethylene chain in the Triton detergent, Triton X 100 (with 9–10 ethylene oxide groups) and Triton X 102 (with 12–13 groups) being more effective, volume for volume, than Triton X 165 (16 groups) and Triton X 305 (30 groups) (Fig. 4). The long-chain detergents are also less effective on a molar basis. Thus 0·2% Triton X 165, which contained 2·22 μmoles/ml., was considerably less effective than 0·1% Triton X 100, which contained only 1·54 μmoles/ml. To summarize, the extent of disruption of the mitochondria can be controlled by the detergent concentration, the mitochondrial concentration, the time the mitochondria are exposed to detergent and the length of the polyoxyethylene chain.

**Isolation of an RNA–lipoprotein complex from disrupted mitochondria**

The disrupted mitochondria were arbitrarily divided into three fractions: fraction A, sedimenting after 30 min. at 10 000g; fraction B, sedimenting after 60 min. at 105 000g; fraction C, the final supernatant. The distribution of phospholipid, RNA and protein was then determined in the

**Fig. 1.** Fall in turbidity, release of RNA and release of protein on disruption of mitochondria with detergent.  
○, Turbidity as measured in the EEL nephelometer; +, visual estimate of turbidity; ○, RNA; △, protein. Mitochondrial suspension in 0·3M-sucrose, containing 0·6 mg. of protein/ml., was treated with increasing concentrations of Triton X 100 and immediately centrifuged at 10 000g for 30 min. RNA and protein were determined in the sediment.

**Fig. 2.** Effect of time on fall in turbidity of mitochondrial suspension in the presence of detergent. Triton X 100 was added (at arrow) to a final concentration of 0·06% (○) or 0·02% (●) to a suspension of mitochondria in 0·3M-sucrose containing 0·62 mg. of protein/ml.

**Fig. 3.** Effect of mitochondrial concentration on disruption of mitochondria by detergent. Concen. of protein (mg./ml.): (A) 0·21; (B) 0·42; (C) 0·63. Mitochondria, in the concentrations shown, were treated with Triton X 100.
The detergent concentration used was 0.2%, v/v.

Conc. of detergent (% v/v)

Percentage of amount in intact mitochondria

Fig. 4. Effect of chain length of detergent on the degree of disruption of mitochondria. Mitochondrial suspension containing 0-27 mg of total N/ml. was treated for 10 min. at 0° with Triton X 100 (O), Triton X 102 ( ), Triton X 185 (△) or Triton X 305 (△) and then centrifuged at 10 000g for 10 min. Total N was estimated in the sediments and expressed as a percentage of the total amount in the mitochondrial fraction. The 0·1% solutions of the various detergents contained 1.54, 1.36, 1.11 and 0.66 µmoles respectively.

Various fractions as the mitochondria were exposed to increasing concentrations of detergent (Fig. 5). As the detergent concentration is raised, protein, RNA and phospholipid disappear from the 10 000g sediment (fraction A) in parallel with the disruption of the mitochondria and the fall in turbidity (cf. Fig. 1). Most of the protein appears in the final supernatant (fraction C) and only about 20% is found in the 10 000g sediment (fraction B). However, this fraction takes a greater share of the phospholipid (about 30%) and nearly half of the total RNA. As a result, it is richer in RNA and phospholipid than either the soluble material or intact mitochondria. More detailed properties of the three fractions are given in Roodyn et al. (1961a, Table 5) and Roodyn et al. (1962, Table 3). (In the experiments published previously the mitochondrial suspension contained 4-5 mg. of protein/ml. and the detergent concentration used was 0·2%, v/v.)

Fraction A (sediment after 30 min. at 10 000g). As this fraction includes unbroken and swollen mitochondria, its precise composition varies greatly with the degree of disruption. In general, it is rich in RNA, phospholipid, succinoxidase and radioactive protein, and poor in malic dehydrogenase if a high ratio of detergent to mitochondrial protein is used for lysis. Because it is then very similar in constitution to fraction B, in later work it has been combined with this fraction by omitting the centrifuging at 10 000g for 30 min. (Fig. 6, Table 1).

Fraction B (sediment after 60 min. at 10 000g 'RNA-lipoprotein complex'). This is rich in RNA, phospholipid, succinoxidase and radioactive protein, and is poor in malic dehydrogenase. With the value for intact mitochondria taken as 1, the relative concentrations of these components were 2·07, 1·40, 1·14, 2·15 and 0·56 respectively (Roodyn et al. 1961a, 1962). The fraction appears as a reddish brown gel that is difficult to disperse in solution. In the visual spectroscope it has a diffuse band in the red and a faint band in the green. After reduction with a trace of sodium dithionite, clear bands appear at 605, 550 and 530 mµ. Treatment with up to 1·0 M NaCl failed to extract any protein or nucleic acid. The precise yield and chemical composition of this fraction

Fig. 5. Effect of detergent concentration on chemical composition of fractions derived from disrupted mitochondria. O, RNA; ×, protein; △, phospholipid. R: recovery. Mitochondrial suspension in 0·3 M sucrose, containing 5·05 mg. of protein/ml. was disrupted with Triton X 100. The mitochondria contained 1·17 mg. of RNA and 20·9 mg. of phospholipid/100 mg. of protein. (A) 10 000g sediment; (B) 105 000g sediment; (C) 105 000g supernatant.
varies with the detergent concentration used, but it usually contains 10–20% of the total mitochondrial protein and has 3–5 mg of RNA and 30–50 mg of phospholipid/100 mg of protein. From its properties, and by analogy with the results of other workers (see Discussion) there is little doubt that this fraction is derived mainly, if not entirely, from the mitochondrial membrane. For convenience, however, in later experiments fractions A and B have been combined and designated the ‘crude RNA–lipoprotein complex’. Together they contain about two-thirds of the total radioactive protein.

Fraction C (supernatant after 60 min at 105 000g). This fraction contains the bulk of the freely soluble material of the mitochondrion, including malic dehydrogenase. It has a relatively low concentration of phospholipid and RNA and has a low specific radioactivity. It has been examined in more detail elsewhere, together with the easily soluble protein fraction that is released during the incubation of the mitochondria (Roodyn et al. 1962).

Sequential release of mitochondrial components by ‘titration’ with detergent

The above-mentioned fractionation had established that the bulk of the radioactive protein was in a fraction rich in phospholipid and RNA but it was not certain to which of these materials it was predominantly bound. The dissociation of radioactive protein from RNA, and its close relation with lipoprotein, was then demonstrated as follows. Mitochondria were exposed to increasing concentrations of Triton X100 and immediately sedimented at 105 000g for 60 min. (Fig. 6). The sequential removal or inhibition of the various components is clearly demonstrated in this way, the order being: malic dehydrogenase, protein, succinoxidase, phospholipid, radioactive protein and finally RNA. The radioactive protein is found to be far more extractable than RNA and only slightly less extractable than succinoxidase and phospholipid. In this connexion it is interesting that the disappearance of succinoxidase activity from the pellet coincides with the removal of phospholipid, so that the ratio of succinoxidase to phospholipid remains constant throughout the experiment.

The difference in behaviour of the various components is shown strikingly if the results are expressed on the basis of ‘relative concentration’, i.e. value/mg of protein divided by value/mg of protein in intact mitochondria (Fig. 7). In Fig. 7, three stages are revealed during the ‘titration’ with detergent: A, the particles show no sign of damage, having identical concentrations of all the components as with the intact mitochondria; B, a pellet is obtained that is rich in phospholipid, RNA, succinoxidase and radioactive protein, but poor in malic dehydrogenase and protein; C, the pellet is rich in RNA but has only residual phospholipid, succinoxidase and radioactive protein. Fraction B is similar in constitution to the RNA–lipoprotein complex referred to above.

Dissociation of crude RNA–lipoprotein complex into RNA-rich and lipid-rich components

From the above results it would be expected that treatment of the material initially insoluble in detergent with more detergent should release phospholipid and radioactive protein, but not RNA. These expectations were confirmed in the experiments given in Table 1. The crude RNA–lipoprotein complex was treated with 50 ml of 0.5% Triton X100 (Expt. 1) and a RNA-rich sediment and a lipid-rich extract were obtained. In Expt. 2 the detergent concentration was raised to 4.5% (v/v). As a result the extracted material had a very high lipid:protein ratio, whereas the residual material was enriched in RNA sevenfold compared with the original mitochondria, and had a very

![Fig. 6. Sequential extraction of components from mitochondria by treatment with increasing concentrations of detergent.](image-url)
low lipid content. The protein in it was considerably less radioactive than the protein in the extracted lipid-rich component.

### Lipoproteins present in lipid-rich component

**Relation to 'structural protein' of Green et al.** (1961b). The crude lipoprotein extracted by the second detergent treatment was precipitated, together with some detergent, by the addition of 25 g. of ammonium sulphate/100 ml. of solution (Table 2). The material obtained was about four times as radioactive as the total mitochondrial protein and had the ratio of RNA:phospholipid: protein 0:7:55:0:44:3. When it was treated with butan-1-ol a precipitate was obtained that was insoluble in 0-1 m-potassium phosphate, pH 7-0. It dissolved slowly in 0-1 N-sodium hydroxide and only partially in 8 m-urea. It could be dissolved in 8 m-urea-0.1 % sodium dodecyl sulphate, however, and, in this solvent, had an absorption maximum at 277 m,m and a minimum at 247 m,m. There was no evidence of a peak at 260 m,m and the ratio \( E_{260}/E_{280} \) was 0-82, indicating a low nucleic acid content. There was negligible absorption at 410 m,m or between 520 and 605 m,m either before or after treatment with sodium dithionite, which suggested that haem derivatives were absent. The material therefore closely resembled the 'structural protein, S.P.' described by Green et al. (1961b) for ox-heart mitochondria.

The procedure of these workers was therefore applied to rat-liver mitochondria (Table 3) and a protein was obtained (fraction J) that had similar solubility properties to that obtained from ox-heart mitochondria by Green and co-workers. It

Table 2. Precipitation of radioactive lipoprotein from lipid-rich extract with ammonium sulphate

Lipid-rich extract was prepared as described in Table 1, Expt. 1, and 25 g. of ammonium sulphate added/100 ml. of extract and the precipitate filtered off. Mitochondrial fraction had 35.9 µc/mg., 2.72 mg. of RNA/100 mg. of protein and 27.8 mg. of phospholipid/100 mg. of protein. Results are means from two experiments.

contained 18% of the total mitochondrial protein and 23% of the total radioactivity. Since the various washings (fractions F–I) were less radioactive than the 'structural protein' it seemed probable that this protein was becoming labelled to a significant extent. However, the detergent mixture used did not extract all the mitochondrial protein, and a greenish brown residue was left (Table 3, fraction C) that contained 10% of the protein and 34% of the total radioactivity. In a modification of the method of Green and coworkers, this residual material was extracted with more detergent, and the ammonium sulphate was added in a stepwise manner (Table 4). A small amount of radioactive protein was extracted by the second detergent treatment, but the residue still contained nearly 30% of the total radioactivity. Since the ammonium sulphate fractionation did not yield any highly radioactive protein, and since the method now closely resembled that developed with Triton X 100 (Tables 1 and 2) it was not modified further.

**Subfractionation on calcium phosphate** (Table 5). The lipid-rich extract was loaded on to a calcium phosphate column (see Methods section). The effluent during loading and washing with 0·02M buffer contained a small quantity of protein with a specific radioactivity 10–15 times that of the total mitochondrial protein (fraction C). Difficulties in analysing the small amount of material in the presence of a large excess of detergent have prevented an accurate chemical analysis of this fraction, but preliminary results indicate that it is poor in RNA but rich in phospholipid. The high radioactivity is not a consequence of the fact that detergent has been precipitated together with protein by trichloroacetic acid during the plating procedure, since mitochondrial protein precipitated with trichloroacetic acid had the same specific radioactivity if detergent was present or absent. Also, a very similar protein fraction isolated from the detergent-soluble proteins (see Table 6, fraction C) had a low specific radioactivity.

1·0M-Phosphate buffer eluted a yellowish brown turbid fraction. After clarification with Triton X 100, the eluted material showed a sharp peak at 410 m, and a broad absorption band between 515 and 600 m. After reduction with sodium dithionite, the peak at 410 m shifted to 415 m and two flat peaks appeared at 520 and 560 m. These results suggested the presence of haem proteins. The specific radioactivity of this fraction varied considerably between experiments, and it is not certain whether the radioactivity present was due to contamination with other fractions.

The material remaining attached to the column was three to four times as radioactive as the total mitochondrial protein. It showed a remarkable degree of binding and was not eluted with molar phosphate saturated with potassium chloride, or even by brief treatment with aq. 0·5% ammonia solution. For chemical analysis of the attached material the calcium phosphate was dissolved in 5% (w/v) trichloroacetic acid and the precipitated material analysed. Usually, however, the material was isolated by dissolving the column in sodium citrate (cf. Salk, 1941), centrifuging to obtain a floating layer of protein, dialysing this and

sedimenting it at 105 000g (see Methods section). The material so obtained (Table 5, fraction 1) is approximately four times as radioactive as the total mitochondrial protein and has the ratio of RNA: phospholipid: protein 0:4:38-0:61-6. The fractionation on calcium phosphate therefore shows that the crude lipoprotein in the lipid-rich component contains several different radioactive proteins and is clearly heterogeneous.

Presence of radioactive lipoproteins in detergent-soluble protein fractions. It had been observed previously during the chromatography of soluble mitochondrial proteins on calcium phosphate that elution with buffer of high molarity removed small quantities of relatively radioactive proteins (Roodyn et al. 1962, Table 4). Because of the properties of the lipid-rich component observed above, it was possible that similar proteins were present. The detergent-soluble protein fraction was therefore loaded on to calcium phosphate (Table 6) and submitted to the same procedure as that given in Table 5. Although the bulk of the protein was not retained by the column, some radioactive material remained attached after washing with molar buffer. It was found to be rich in phospholipid and poor in RNA (RNA: phospholipid : protein, 0:2:57-2:42-6). When the column was dissolved in sodium citrate the attached lipoprotein behaved similarly to that obtained from the lipid-rich component described above. Treatment of the final sediment (Table 6, fraction H) with butan-1-ol gave an insoluble protein, as with the lipid-rich component.

DISCUSSION

The disruption of the mitochondria with surface-active agents undoubtedly results from interaction of the detergent with the mitochondrial membrane. It is not known whether the interaction is primarily with lipid, with non-polar side chains in the proteins making up the membrane (Green, Tisdale, Criddle & Boek, 1961a) or with both. The neutral detergents should not act by ionic interactions and hence should produce less denaturation of the protein than cationic or anionic detergents. Glassman (1950) observed that the inactivation and precipitation of botulinum-toxin protein produced by charged detergents did not occur with the neutral detergent Triton A20. Neutral detergents have been used by several workers to study the release of enzymes from subcellular particles (e.g., Walker & Levvy, 1953; Feinstein, 1959; Bendall & de Duve, 1960) without any reports of enzyme inactivation. Use of Triton X100 for extraction did not inactivate malic dehydrogenase and it was possible afterwards to obtain 100-fold purification of the enzyme (Roodyn et al. 1962). The fact that the protein could be readily adsorbed on to calcium phosphate columns from detergent solutions without prior removal of the detergent indicated that strong electrovalent links between protein and detergent were lacking. The interaction with detergent is determined not only by the absolute concentration of detergent (Figs. 1, 5 and 6) but also by the ratio of detergent to mitochondrial protein (Fig. 2). This is a general phenomenon of interaction between detergents and proteins (Putnam, 1948). The effect of chain length of detergent (Fig. 4) would also suggest that the mitochondrial lysis not only depends on the absolute concentration of detergent but requires some interaction between detergent and mitochondria. In the activation of latent adenosine triphosphatase of rat-liver mitochondria by saturated fatty acids, Pressman & Lardy (1956) observed that a chain length of 14 was optimum. Thus it seems likely that steric factors are involved.

in reactions of surface-active materials with the mitochondrial membrane.

The sequence of events as the mitochondria are exposed to increasing concentrations of detergent may now be described. The first clear effect is the release of soluble mitochondrial protein. It is probably an over-simplification to imagine that the mitochondrion simply ‘bursts’ on addition of detergent. Watson & Siekevitz (1956) exposed rat-liver mitochondria to increasing concentrations of sodium deoxycholate. The mitochondrion first swelled considerably and the inner membrane and cristae mitochondriales appeared at one side of the outer membrane. The particles then shrank and the matrix cleared considerably. Both the inner and outer membranes then became progressively less electron-dense until the preparation finally consisted of empty vesicles. At no stage was there sudden disruption of the mitochondrial membrane, but rather there seemed to be a steady extraction of material from it. This accords well with the above-mentioned observations. If the mitochondria merely burst when the detergent had reached a critical concentration, one would expect a sudden release of soluble protein, leaving residual material of constant composition. However, the release of protein is spread out over a fairly wide range of detergent concentration (Fig. 6), and the composition of the insoluble fragments is found to vary as the detergent concentration is raised (Figs. 5 and 7). In addition, the detergent-soluble fraction contains a radioactive lipoprotein very similar in properties to material that can be extracted from the membrane or ‘insoluble’ component (Table 6). This suggests that a range of particles, from free proteins down to large lipoprotein aggregates, is liberated by the detergent. The definition of ‘soluble’ is clearly operational and is often used synonymously with ‘material not sedimenting after 60 min. at 100 000 g’.

Having lost its main easily soluble component the mitochondrion is now relatively rich in RNA, phospholipid and succinoxidase and appears as a reddish brown translucent pellet. This has been described above as the ‘RNA–lipoprotein complex’, although it should be stressed that the amount of RNA is small compared with the amount of lipid. Other workers have obtained similar fractions from liver mitochondria, disrupted by a variety of methods. For example, Hogeboom & Schneider (1950) disrupted mitochondria by rather prolonged treatment with sonic vibrations and found that the material sedimenting after 148 000 g for 30 min. contained succinoxidase and cytochrome oxidase. By using shorter treatment with sound waves, McMurray, Maley & Lardy (1958) obtained a similar fraction consisting of vesicles 0·05–0·5 μ in diameter capable of carrying out oxidative phosphorylation. Cooper & Lehninger (1956) used digitonin to prepare a sub-particle also capable of oxidative phosphorylation. This material was rich in bound respiratory enzymes (Devlin, 1959) and appears under the electron microscope as aggregates of small vesicles 200–500 Å in diameter (Siekevitz & Watson, 1957). Harel, Jacob & Moulé (1957) obtained a fraction rich in RNA, phospholipid and succinoxidase from mitochondria disrupted by freezing and thawing. Particles capable of oxidizing NADH have been obtained by grinding mitochondria with alumina and centrifuging the disrupted mitochondria for 60 min. at 100 000 g (Baltscheffsky, Fudge & Arwidsson, 1960). Siekevitz & Watson (1956) used sodium deoxycholate and observed that the material sedimenting after 60 min. at 105 000 g was rich in succinoxidase, phospholipid and RNA. By correlation with electron microscopy (Watson & Siekevitz, 1956) it was clear that this fraction was essentially derived from the mitochondrial membrane. Since these workers ascribed the presence of RNA in this fraction to contaminant microsomal material, it cannot be certain that the RNA in the RNA-lipoprotein complex is derived from the mitochondrial membrane (see below, however).

Further extraction with detergent removes material in which the ratio of phospholipid to protein is high (1·5 or 2·1) and which contains very little RNA (Tables 1 and 2). The extraction of phospholipid proceeds in parallel with the inactivation of succinoxidase (see also Nygaard, 1953). The extracted material probably contains several different proteins, including haem proteins, as revealed by fractionation with calcium phosphate. However, if the crude extract is precipitated with ammonium sulphate and treated with butan-1-ol, an insoluble protein is obtained that is very similar to the ‘structural protein’ of ox-heart mitochondria described by Green et al. (1961b). The application of the method of Green et al. (1961b) for the preparation of structural protein from rat-liver mitochondria was not entirely successful because of incomplete extraction of the mitochondria (Tables 3 and 4), but the results were consistent with the presence of a protein similar to that obtained from ox heart and with it becoming labelled to a significant extent in vitro. It is reasonable to suppose therefore that the more prolonged detergent treatment removes normally insoluble lipoprotein, the protein portion of which has the properties of an insoluble structural protein after treatment with butan-1-ol. The extracted lipoprotein fraction has the highest rate of labelling in vitro of all the mitochondrial subfractions studied.

The experiments reported above have provided some more information about the properties of the small amount of RNA found in the mitochondrial
fraction. Since repeated washing of mitochondria failed to remove all the RNA but did remove added microsomes, and since the incorporation process differed in several major respects from the microsomal system (e.g. lack of requirement for cell sap) it seems reasonable to infer from previous experiments (Roodyn et al. 1961 a) that the RNA present in the mitochondrial fraction is not simply due to microsomal contamination.

The bulk of the RNA in the mitochondrial fraction is resistant to extraction by detergent (Fig. 7) and the residue after prolonged extraction is relatively rich in RNA (containing 7–10% of RNA) and poor in phospholipid (Table 1). It is not known if the residual mitochondrial RNA is present as ribosomes. Certainly no material in which the RNA: protein ratio approaches unity has been isolated from mitochondria. In this connexion, a ribonuclease-resistant incorporation system, with properties similar to the mitochondrial system, has been isolated from the light microsomal fraction (Prosser, Hird & Munro, 1961). Similar fractions, rich in "smooth membranes", contain significant amounts of RNA (Moule, Rouiller & Chauveau, 1960; Chauveau, Moule, Rouiller & Schneebeli, 1962). The existence of RNA in the mitochondrial membrane, with a role in protein synthesis, is therefore feasible (cf. Hendler, 1962). However, it is clear that more work is required on the properties of mitochondrial RNA before this possibility can be established with certainty.

The results of the above-described fractionation studies may now be considered in relation to mitochondrial-protein synthesis. The most striking conclusion is that incubation in vitro results in labelling of insoluble lipoprotein probably derived from the mitochondrial membrane. There is some labelling of protein bound to RNA but it is less than that of the lipoprotein. The rate of labelling of the truly soluble proteins (e.g. malic dehydrogenase and cytochrome c) is negligible (Roodyn et al. 1962). However, there is some evidence that the pattern of labelling in vitro is very different. Marsh & Drabkin (1957) observed good labelling of cytochrome c in vivo. Fletcher & Sanadi (1961) showed that the turnover rates in vivo of cytochrome c, soluble protein, residual protein and lipid of rat-liver mitochondria were identical, and, in confirmation of this, Dr K. B. Freeman in our Laboratory has recently observed that the rate of labelling in vivo of mitochondrial subfractions prepared by the methods in this paper are not strikingly different. Such results suggest that the various components of the mitochondria are assembled simultaneously in the living cell.

To bring these observations together, it could be imagined that the assembly of the mitochondrion proceeds by a reversal of the events observed during its degradation. It has been shown above that the main stages of the disruption by detergent are most probably those in Scheme 1.

![Scheme 1](image)

Reversal of the process in Scheme 1 might occur as follows. The primary template is a RNA-protein fraction (possibly derived from the nucleus; Roodyn, Reis & Work, 1961 b). On this are synthesized the structural proteins, which have specific binding sites for lipid and certain haem-proteins, as described by Criddle, Bock, Green & Tisdale (1961). The result is the formation of a RNA-lipoprotein complex, containing attached respiratory enzymes arranged in their correct relative positions, and possibly corresponding to the mitochondrial 'monomer' or mitochondrial sub-unit described by Green (1959). The sub-units then polymerize to form the mitochondrial membrane, thus enclosing the soluble mitochondrial proteins. The soluble proteins and the bound respiratory enzymes of the membrane are synthesized on the ribosomes, in a region of the endoplasmic reticulum close to the site of assembly of the mitochondria. The mitochondrial RNA controls only the synthesis of the insoluble structural proteins of the membrane. In vivo, therefore, simultaneous labelling of all components could occur. Incubation of mitochondria in vitro, however, would result only in labelling of the insoluble structural material. Such a view should be regarded only as a preliminary working hypothesis, however, since the synthesis of a well-characterized structural protein of high purity has not yet been demonstrated in this work.

**SUMMARY**

1. Rat-liver mitochondria were incubated in vitro with radioactive valine and the distribution of radioactive protein was determined in mitochondrial subfractions obtained after disruption with detergent.

2. The extent of disruption by Triton detergents was affected by the chain length of the detergent,
the detergent concentration, the mitochondrial concentration and the time of exposure of the mitochondria to detergent.

3. By variation of these factors it was possible to obtain controlled disruption and to extract the various components of mitochondria in a sequential fashion.

4. By differential centrifuging of the disrupted mitochondria, a fraction rich in respiratory enzymes, ribonucleic acid and phospholipid, and containing the bulk of the radioactive protein, was obtained. The fraction was probably derived from the mitochondrial membrane.

5. Treatment of this fraction with more detergent separated it into a ribonucleic acid-rich component and a lipid-rich component, the latter having protein of higher specific radioactivity.

6. Treatment of the crude lipoprotein in the lipid-rich component with butan-1-ol gave a protein similar in properties to the ‘structural protein’ of ox-heart mitochondria described by other workers.

7. Fractionation of the lipid-rich component on calcium phosphate revealed the presence of at least two radioactive proteins.

8. It is concluded that the major site of incorporation of amino acids, in vitro, is into insoluble lipoprotein, probably derived from the mitochondrial membrane.

9. An hypothesis to explain the pattern of labelling observed in vitro is presented.

The author is grateful to Miss J. S. Coomber and Miss A. M. Pearson for technical assistance and to Dr T. S. Work for his kind interest and guidance in this work.
